Estimating Equilibrium in Health Insurance Exchanges: Price Competition and Subsidy Design under the ACA

JOB MARKET PAPER

Abstract. The recent US health care reform (Patient Protection and Affordable Care Act; ACA) instituted a subsidy program that provides discounts on health insurance premiums for low-income households. Any evaluation of the ACA or other related programs necessitates the estimation of consumer demand and the way subsidies affect insurers’ costs and market power. To do so, I combine data from the first year of the Californian ACA exchange — where 90% of buyers receive federal subsidies — with an equilibrium model of insurance demand and imperfect competition. Taking advantage of ACA pricing restrictions and regional variation in market composition, I identify and estimate demand and cost, and then assess outcomes under the current and alternative subsidy designs. I find that, compared to a voucher program, the current design leads to a substantial increase in market power: Price increases do not translate one-for-one to premium increases, and this leads to a less elastic demand response, hence higher markups. I also show that varying subsidies by age could be an attractive possibility: Increasing participation of younger individuals — estimated to be cheaper to cover and more price sensitive — reduces market power and average cost. I estimate that this implies that participation is 30% greater and per-insured public expenditure is 15% lower when compared to the current subsidy design.

1 Introduction

The objective of many public welfare programs is to guarantee access to specific goods and services, with medical care being a prominent example along with housing, food, and education. One common method to achieve this is the provision of consumption subsidies. The low-income subsidy introduced by the 2010 US health care reform (Patient Protection and Affordable Care Act; ACA) provides a recent example. Since 2014, under this program the federal government transferred approximately $40 billion per-year to private insurers, providing discounts on health insurance premiums to more than 10 million citizens. Although important for the success of this reform and for other related programs, the way in which the design of health insurance subsidies affects market outcomes (e.g. coverage levels and public spending) is still unexplored.

My goal in this paper is to study the dependence of equilibrium outcomes on how subsidies interact with three important features of the private health insurance market: demand from low-income buyers, insurers’ price competition, and selection — correlation between a buyer’s willingness to pay and ex-ante expected health cost. Characteristics of demand determine the extent to which subsidies increase buyers’ participation. Pricing incentives and market power of imperfectly competitive insurers react to these changes in demand, but also to corresponding changes in average cost driven by differences in the composition of enrollment pools.

To account for these effects, and compare different subsidy designs, I combine data from the first year of the Californian ACA marketplace — in which 90% of the 1.4 million buyers receive federal subsidies — with a model of insurers’ competition customized to include subsidies and other ACA regulations. I discuss identification of demand and supply primitives exploiting variation in the regional composition of buyers, and assuming equilibrium pricing. I then use these estimates and the model to carry on quantitative comparisons of different designs of subsidy programs in terms of equilibrium prices, enrollment, markups, and public spending. Within this framework my results suggest that the ACA subsidy scheme leaves room for improvements that are quantitatively significant and consistent with theoretical predictions. The alternatives I consider can potentially reduce insurers’ market power, and increase incentives for the participation of young buyers that directly affects average cost — and thus prices and public spending — in the newly created state-level marketplaces.

Specifically, I focus on two important design decisions: The first is whether or not price discounts should be fixed (“vouchers”), or calculated as a function of market prices (“price-linked”); the second is whether discounted prices should be equal across all buyers with the same income, or adjusted to buyers’ age. Both decisions are closely related to the ACA design, which features price-linked subsidies by which, given income, discounted prices do not vary by age.

The theoretical implications of these decisions are discussed in Section 2. For this I use a simple model of differentiated insurers competing over buyers of different age, and where — similarly to
the ACA — regulations limit price-adjustments across age. The model highlights how the impact of different subsidy designs depends on the primitives of the market, and particularly on the intensity of price competition and the heterogeneity in price elasticity of demand and cost across age groups.

In Section 3 I present regulatory details and data on prices and enrollment from the first year of the Californian exchange. This is the largest among ACA marketplaces, where subsidy eligible buyers can choose between different coverage options offered by a set of participating insurers. This provides me with an attractive setup to estimate demand for coverage among the low-income uninsured, since the pre-reform period did not offer a reliable, large-scale environment in which buyers from this segment of the population were making active choices.\(^1\) I combine this novel dataset with a discrete-choice model of insurance demand and ACA-regulated price competition in Section 4; this combination allows me to identify and estimate primitives under the status-quo, and simulate equilibrium after changing the subsidy scheme while keeping other regulations fixed.

Identification of demand presents a common challenge, requiring me to observe cross-market price variation plausibly uncorrelated with unobserved variation in the attractiveness of a product. As I discuss in Section 5, in the context of ACA marketplaces existing regulations point directly toward a suitable instrumental variable strategy. The ACA only allows insurers to set one base price for every insurance plan in a given market (group of counties), and pre-determined pricing schedules are used to translate this base price to the premium faced by buyers of different age and income. Because this regulation links profits across heterogeneous buyers to the same univariate decision, when setting base prices insurers must consider the composition of buyers.\(^2\) Indeed, age-income composition is a strong predictor of cross-market variation in prices in my data. Consequently, assuming that individual preferences are independent from market composition — e.g. willingness to pay among 21-year-olds is independent from the number of uninsured 64-year-olds — I use age-income composition to instrument for price and obtain consistent estimates of demand for various age and income groups.

For identification of insurers’ costs I rely instead on the combination of equilibrium assumptions with existing pricing regulations. Specifically, in Section 5 I present conditions under which the well-known inversion of first-order optimal pricing conditions (see e.g. Rosse, 1970; Bresnahan, 1981; Berry, Levinsohn, and Pakes, 1995) can be extended to models of regulated insurance supply to identify sellers’ costs. To gain intuition, suppose that insurers cannot vary price by age. Once I obtain demand estimates, I construct marginal revenues for every observed insurance contract.

---

\(^1\) Before the ACA, the most similar environment in which subsidies were provided to buyers with income between 100-300% of the federal poverty level was the Massachusetts’ Connector. However, under the Commonwealth Care Program these low-income buyers were not making active choices, but instead automatically assigned to a plan based on their income (see e.g. Ericson and Starc, 2015).

\(^2\) As we discuss in Orsini and Tebaldi (2015), the automatic age-rating adjustments mandated by the ACA apply the same age gradient — or standard age-rating curve — across different markets. As long as this constant factors cannot perfectly capture age-differences in prices that would result if age-based price discrimination was allowed, regional variation in the age-composition of potential buyers becomes a relevant determinant of constrained prices.
Equilibrium pricing implies that marginal revenues are equal to marginal cost, which results from a combination of unobserved cost across different age groups. Hence, assuming that age is the only determinant of insurers’ expected cost, to estimate age-driven cost heterogeneity I compare marginal revenues/cost between contracts whose marginal buyers are predominantly “old” and contracts whose marginal buyers are instead predominantly “young”. More precisely, variation in age-composition of marginal buyers — which can be derived after estimating age-specific demand curves — can be used to identify the impact of buyers’ age on insurers’ expected costs. A stronger result relegated to Appendix C provides conditions for identification when buyers’ cost may also differ in their preferences along unobservable dimensions; this follows from results in Berry and Haile (2014) combined with a constructive proof adapted from Somaini (2011, 2015).

In Section 6 I present the resulting estimates. For demand I find that price sensitivity decreases in age and income, in line with common wisdom and existing literature on insurance demand; (e.g. Auerbach and Ohri, 2006; Chan and Gruber, 2010; Bundorf, Levin, and Mahoney, 2012; Handel, 2013; Ericson and Starc, 2015). For example, own-price elasticity varies from 3 for low-income young adults to 1 for high-income over 45. More importantly, a $100 increase in all prices implies a drop in overall coverage of 12% among low-income under 45, 4% among low-income over 45, and less than 3% among high-income. Estimated cost heterogeneity across age groups is also sizable, and consistent with existing evidence from the Medical Expenditure Panel Survey. On average, the expected cost of covering a buyer older than 45 on a zero deductible plan is approximately $8,100 per-year, dropping to $2,460 for younger buyers. Estimated costs also vary across insurers, by up to $600 per-person, and across different regions of the state.

These demand and cost estimates are the main inputs for my counterfactual analysis in Section 7, where I start by comparing fixed vouchers to the price-linked discounts adopted under the ACA. The current scheme calculates discounts from market prices to ensure that buyers do not pay more than a predetermined amount. As a consequence, if all prices increase by $1, low-income buyers do not face any price change, while government expenditure increases by $1 per buyer. This creates incentives for insurers to set higher prices than if discounts were instead predetermined vouchers. Indeed, my simulations imply that equilibrium insurers’ markups are 15% lower if the current subsidy scheme is replaced by a voucher; under this alternative discounts are of equal amount to those ACA ones but are not adjusted to insurers’ decisions. This reduction in markups corresponds to a lower per-buyer spending by the government of approximately 5%, while coverage among low-income buyers is 10% higher than under the status quo.

The second design decision I consider is whether the subsidized price that a buyer pays should vary not only with her income, but also her age. Intuitively, a higher share of young buyers in the market raises elasticity and reduces average cost, lowering equilibrium prices, so that more generous subsidies to younger buyers could increase coverage for all age groups, and reduce per-insured public spending. Consistently with this idea, I find that, by raising vouchers to under 45
by $400 and lowering those to over 45 by $200, enrollment among the young raises by 50% while enrollment of the older is approximately unchanged. The reason is that, in equilibrium, a higher share of young enrollees reduces average cost by 15%, and markups by more than 20% (young buyers have also higher elasticity). Hence prices are lower, and this offsets the $200 reduction in the subsidy to the older group. At the same time, per-insured government expenditure is also reduced by approximately 15% ($600 per-buyer-year).

This paper contributes to the literature along several directions, adding to recent work on the early years of the ACA, more broadly on regulated competition in private health insurance, and to the literature on estimation of demand-supply models of insurance.

Existing work with ACA data that, like me, evaluates the impact of the reform and the role of different regulations includes Kowalski (2014), Dafny, Gruber, and Ody (2015), Dickstein et al. (2015), and Orsini and Tebaldi (2015). One common feature of these papers is to exploit cross-sectional variation in outcomes across states, or state-level variation over time, without adopting any explicit demand-supply model. Here, instead, I use more granular variation in prices and enrollment within a single state-level marketplace, and develop an empirically tractable model that allows me to account for imperfect competition and for the equilibrium implications of different parts of the ACA regulatory framework.3

With pre-reform data, other papers study regulations that closely resemble those introduced by the ACA. Many of them use data from the Massachusetts’ health exchange, a setting similar to ACA marketplaces.4,5 In this context, Hackmann, Kolstad, and Kowalski (2015) measure the welfare effect of an insurance mandate, and Ericson and Starc (2015) develop and estimate a demand-supply model to study several ACA-like regulations, with main focus on the effect of age-based price adjustments for high-income buyers. My work complements theirs by focusing on the low-income segment of the population — not making active choices in the MA context —, and precisely studying the subsidy program for these buyers. Relating more closely to one of my counterfactuals, and also using information from the pre-ACA Massachusetts’ exchange, ongoing work by Jaffe and Shepard (2014) provides back-of-the envelope calculations suggesting a 12.5% reduction in markups if vouchers were adopted instead of the current ACA price-linked

3Here I focus on a limited number of subsidy design alternatives, but my model could also be used to evaluate, for example, changes to age-rating rules, the implementation of the mandate penalty, or changes to the set of contracts that insurers’ must offer and/or subsidized buyers are allowed to choose from.

4See also Long et al. (2010); Ericson and Starc (2012b,a, 2013, 2014); Shepard (2014).

5Other studies combine theoretical results and simulations: the impact of insurance mandates and minimum coverage provisions is studied by Azevedo and Gottlieb (2014); the relationship between risk-adjustment and insurers’ competition by Mahoney and Weyl (2014); the long-run welfare impact of community rating rules by Handel, Hendel, and Whinston (2015); the interaction between exchange design and labor markets by Aizawa (2015). Differently from my work, these papers abstract away from various aspects of market structure and imperfect competition observed in the US insurance market (see e.g. Dafny, 2010; Starc, 2014), and quantifications use data or estimates from employer-sponsored insurance (e.g. Einav, Finkelstein, and Cullen, 2010a; Handel, 2013).
subsidy. Although our methodological approaches — both theoretical and econometric — and specific markets are different, we find similar effects.

Even outside the ACA setting there is a growing literature adapting industrial organization techniques to analyze the interaction between regulations and supply behavior of private health insurers. The cases of Medicare Advantage, Medicare Part D, Medigap, and Medicaid are the main focus of, among many others, Duggan and Hayford (2013), Curto et al. (2014), Duggan, Starc, and Vabson (2014), Starc (2014), Clemens (2015), and Decarolis, Polyakova, and Ryan (2015). Notably, Decarolis (2015) shows distortions of insurers’ decisions due to the design of subsidies in Medicare Part D, and in a broad review of this literature Einav and Levin (2015) explicitly discuss the importance of properly accounting for market power when designing these programs.

Lastly, my paper contributes from a more methodological perspective to the empirical literature on selection markets. Many aforementioned papers and others in this literature identify heterogeneity in risk and preferences relying on the availability of cost data, or using external surveys.6 Here instead, with an approach that is similar in spirit to the one of Lustig (2010) — although our estimations and implementations differ — I adapt to this context the classical inversion of first-order equilibrium conditions (c.f. Rosse, 1970; Bresnahan, 1981; Berry, Levinsohn, and Pakes, 1995) to identify cost-heterogeneity across buyers. Beyond my specific application, Appendix C combines results in Berry and Haile (2014) and a proof adapted from Somaini (2011, 2015) to provide sufficient conditions for nonparametric identification of costs varying with buyers’ preferences when cost heterogeneity is not observed.

2 Subsidy design in health insurance

I start by introducing a simple theoretical framework in which different subsidy designs, combined with insurers’ market power and pricing restrictions, may result in different equilibrium outcomes. My main purpose here is to highlight how, given properties of buyers’ preferences and costs that will be estimands in my application, alternative subsidy designs can be ranked in terms of the corresponding equilibrium prices, coverage levels, and public spending.

2.1 Setup

Consider a market with \( J \) health insurers. For now, each offers just one insurance plan \( j = 1, \ldots, J \), with \( j = 0 \) denoting the outside option. I relax this assumption and consider multi-plan insurers later in the context of my application. Non-price characteristics of each plan are fixed, and their generosity of coverage is the same, so differences in demand across plans are driven by brand preferences and attributes of the provider networks.

---

6See also Einav, Finkelstein, and Cullen (2010a); Einav, Finkelstein, and Schrimpf (2010b); Bundorf, Levin, and Mahoney (2012); Einav, Finkelstein, Ryan, Schrimpf, and Cullen (2013); Handel (2013); Starc (2014).
Buyers are of one of two types, say young and old, denoted by \( \tau = Y, O \), and I will use \( G(\tau) \in [0, 1] \) to denote the fraction of type \( \tau \) buyers in the market. Different types of buyers may have different health status (and thus cost for the insurer) and demand for insurance coverage. In particular, when selling coverage to a type \( \tau \) buyer, insurer \( j \) expects to incur a cost equal to \( C^j_\tau \). Demand is defined by \( \sigma_j(P, \tau) \), a function indicating the probability that a buyer of type \( \tau \) chooses \( j \) when prices are \( P = (P_1, ..., P_J) \). I assume that \( \sigma_j(P, \tau) \) is strictly decreasing in \( P_j \), and that it is continuous and differentiable. I also use \( \eta^\tau_{jk} \equiv \left| \frac{\partial \sigma_j(P, \tau)}{\partial P_k} \right| / \sigma_j(P, \tau) \) to denote the semi-elasticity of demand for \( j \) by type \( \tau \) buyers with respect to the price of plan \( k \); in this section this is treated as constant, another assumption that I relax later in my empirical application.

As an extreme example of limits to price discrimination (similar to those mandated by the ACA), insurers cannot vary prices by \( \tau \), so each sets a single price \( P_j \) that applies to all buyers. In this sense, heterogeneity in demand and cost across buyers with different \( \tau \) is used to model selection; even if observable, the type of a buyer is not priced.

Expected profits are then a weighted average of profits across the two types:

\[
\Pi_j(P_j, P_{-j}) = G(Y) \cdot [\sigma_j(P, Y) \cdot (P_j - C^Y_j)] + G(O) \cdot [\sigma_j(P, O) \cdot (P_j - C^O_j)].
\] (1)

In what follows, I assume complete information, and that prices form a Nash Equilibrium. That is, each insurer \( j \) sets its price \( P_j \) to maximize \( \Pi_j(P_j, P_{-j}) \) taking \( P_{-j} \) as given. I also maintain the assumption that (primitives are such that) prices are strategic complements, so that equilibrium comparative-static results from Vives (1990) can be applied.

### 2.2 Subsidies

To consider the effect of a subsidy program, let a subsidy design be a function \( S(P, \tau) > 0 \), such that type \( \tau \) buyers face the discounted price vector \( P - S(P, \tau) = (P_1 - S(P, \tau), ..., P_J - S(P, \tau)) \). This will change demand by both types, from \( \sigma_j(P, \tau) \) to \( \sigma_j(P - S(P, \tau), \tau) \), and will have a corresponding effect on profits, equilibrium prices, and government expenditure.

I consider a situation in which the government tries to increase coverage for both young and old individuals, and, given coverage levels, to minimize spending per-buyer. Therefore, the key inputs to the subsidy design problem are the effects of different \( S(\cdot, \cdot) \) on equilibrium coverage levels and on expected spending; shedding light on these effects is the primary goal of this paper.

For every chosen design the equilibrium price vector (pre-subsidy) \( P^* \) is such that, for every product, the price is the sum of average cost and markup. Characteristics of demand and cost across different types of buyers determine how average cost and markup depend on the chosen subsidy design. To see this formally, let \( \alpha^S_j(P) \) be the share of young buyers of plan \( j \) when the
subsidy design $S$ is adopted and prices are $P$:

$$\alpha^S_j(P) = \frac{G(Y)\sigma_j(P - S(P,Y), Y)}{G(Y)\sigma_j(P - S(P,Y), Y) + G(O)\sigma_j(P - S(P,O), O)}.$$  \hfill (2)

I use this to define the corresponding average cost — $AC^S_j(\cdot)$ — and markup — $MK^S_j(\cdot)$ — functions under $S$ (see Appendix A1 for detailed derivations):

$$AC^S_j(P) = C^Y_j \cdot \alpha^S_j(P) + C^O_j \cdot (1 - \alpha^S_j(P)),$$

$$MK^S_j(P) = \frac{1 - \left(\alpha^S_j(P) \cdot (1 - \alpha^S_j(P)) \left(\eta^O_j - \eta^Y_j\right) \left(C^Y_j - C^O_j\right)\right)}{\eta^Y_j \alpha^S_j(P) + \eta^O_j (1 - \alpha^S_j(P))}.$$  \hfill (4)

Then, $P^{*,S}$ is an equilibrium under $S$ if for each $j$

$$P^{*,S}_j = AC^S_j(P^{*,S}) + MK^S_j(P^{*,S}),$$ \hfill (5)

so that the problem of the government — if cost and demand primitives are known — amounts to choosing $S$ knowing that prices will then satisfy this equilibrium condition, and coverage and spending will respond accordingly.

**Targeted or non-targeted subsidies?** A first comparison is between a non-targeted subsidy, for which the subsidy does not depend on $\tau$, so $S(P, \tau) = S(P)$, in contrast to a targeted subsidy that does. To compare the two, I first consider a situation in which the government uses a non-targeted voucher, fixing an amount $V > 0$ such that $S(P, \tau) = V$. The alternative is a targeted voucher for which $\hat{S}(P, \tau) = \hat{V} \tau$, with $\hat{V} > V > \hat{V}^O$.

For any given $P$, the composition of buyers under the two schemes differs, with $\alpha^S_j(P) < \alpha^S_j(P)$. Hence, as I formalize in Proposition 1 in Appendix A2, if young buyers are cheaper to cover and more price sensitive, i.e. $C^Y_j < C^O_j$ and $\eta^Y_{jk} > \eta^O_{jk}$ for all $j$, all $k$, it is possible that $\hat{S}$ implies lower average cost and markups:

$$AC^S_j(P) > AC^S_j(P), \quad MK^S_j(P) > MK^S_j(P), \quad \text{for all } P, \text{ all } j.$$  \hfill (6)

Hence, replacing $S$ with $\hat{S}$ can induce an equilibrium with lower prices, $P^{*,\hat{S}} < P^{*,S}$. Moreover, if these price reductions are larger than $V - \hat{V}^O$ (the amount by which discounts to old buyers are lowered under $\hat{S}$), coverage is higher for all buyers, and spending per-buyer is lower.

The possibility to increase quantities among all buyers by tailoring subsidies to heterogeneity in demand and cost is a peculiar feature of selection markets, and one of my main points in this paper. This mechanism would in fact not be present in a “non-selection” market in which $C^Y_j = C^O_j$: Replacing $S$ with $\hat{S}$ would not lower average cost, and old buyers would generally be worse off.
Price-linked discounts or vouchers? A second relevant design decision is whether subsidies should be ex ante fixed by the regulator, or computed ex post as a function of market prices, as it is currently done under the ACA (see Section 3). Practically, one can consider a scheme $S$ with price-linked discounts, for which $\frac{\partial S(P, \tau)}{\partial P_j} > 0$ (for some $j$), or a voucher program where instead $\frac{\partial S(P, \tau)}{\partial P_j} = 0$ for all $j$ and all $P$.

Price-linked discounts may be desirable if the government — not knowing demand and cost primitives — is unable to predict price. Adjusting subsidies to prices reduces then the possibility that discounts are too low (or too high) than what would be necessary to induce a target coverage level. However, adjusting subsidies to prices can distort insurers’ incentives, and lead to an equilibrium with higher prices and higher spending by the government than what would result if subsidies were ex ante fixed. The intuition is straightforward: If price increases are partly covered by discount adjustments, insurers maximize profits as if buyers were less price sensitive, and thus have additional incentives to set higher prices.

I formalize this in Proposition 2 in Appendix A2, where I show that, as long as $C^Y_j < C^O_j$, and $\eta^Y_{0j} > \eta^O_{0j}$, for all $j$ — i.e. once again young buyers are cheaper to cover and more price sensitive —, a price-linked subsidy design $S(P, \tau)$ necessarily leads to higher equilibrium prices than a voucher $\tilde{S}(P, \tau) = \tilde{V}^\tau = S(P^*, S, \tau)$. The magnitude of this distortion decreases with the intensity of price competition and with the degree of horizontal differentiation in the market.

2.3 Relevant primitives

The previous discussion highlights qualitative effects of different subsidy design decisions. Heterogeneity in cost and preferences across buyers, and how this interacts with pricing restrictions, are key to determine the direction and magnitude of these differences. Moreover, the number of insurers and the corresponding degree of price competition are also essential to predict how changes to a given design may imply a different equilibrium.

To study these effects in the context of ACA marketplaces, I introduce relevant institutional details and data from the Californian exchange. I then adapt the model to this setting, and — maintaining fixed pricing regulations and market structure — obtain estimates of demand and cost primitives that allow me to quantify the above theoretical predictions.

3 ACA exchanges

3.1 Institutional context and federal regulations

As of 2013, 17 percent of US citizens younger than 65 did not have health insurance coverage. Affordability of the annual premium was a prominent reason why those uninsured did not purchase coverage in the private market, and this was one of the main motivations for the ACA.
In 2014, the ACA instituted health insurance exchanges in each of the fifty states. An exchange is a market in which private insurers offer a variety of coverage options, and the federal government provides subsidies for low-income participants. Indeed, in the first two years of their operation, approximately 90 percent of buyers on these exchanges received premium subsidies, associated with annual government disbursements of approximately $40 billion.

ACA exchanges operate in each state separately, but they all follow similar institutions and regulations. Each state is divided into geographic rating regions — groups of counties or zipcodes — defining the level at which decisions by buyers and insurers take place. Every spring, insurers announce their interest in offering plans in each region in the subsequent calendar year. Entrants undergo a certification process, after which they offer different coverage options, classified into five coverage levels: Minimum Coverage, Bronze, Silver, Gold, and Platinum. Minimum Coverage indicates plans with very high deductible, which cannot be purchased by subsidized buyers, nor by buyers older than 35. The four metal tiers represent increased coverage options, and are ordered by an estimate of the actuarial value of their coverage: 60% for Bronze, 70% for Silver, 80% for Gold, and 90% or more for Platinum plans.

Federal law requires each participating insurer to offer at least one Silver and one Gold plan, but does not specify the precise combination of deductible and co-pays that lead to these coverage levels. Certain states, including California which is my focus later in this paper, have stricter regulations. They specify the full coverage details and mandate insurers to offer all five coverage levels in each region at which the insurer offers plans. In these exchanges, insurers are differentiated only in their brand name, the structure of their provider networks, and the associated premiums.

Products and prices are set (and made public) at the end of every summer, and individuals can then compare and purchase plans in their region during the “open enrollment” period each fall. Coverage then lasts for the subsequent calendar year.

Pricing regulations. One important provision of the ACA is that insurers are not allowed to arbitrarily vary prices depending on buyers’ observable characteristics. The only characteristic that affects annual premiums is the buyer’s age, but even this adjustment is done in a pre-specified way. That is, each plan $j$ offered in region $r$ is associated with a single base price $b_{jr} > 0$, which is then translated to age-specific premiums using given age adjustment factors $A^r$, equal for all products:

$$P^r_{jr} = A^r \cdot b_{jr}. \quad (7)$$

In California, for example, it is required that the providers include ten essential categories: (1) ambulatory patient services, (2) emergency services, (3) hospitalization, (4) maternity and newborn care, (5) mental health and substance use disorder services, (6) prescription drugs, (7) rehabilitative services and devices, (8) laboratory services, (9) preventive services / chronic disease management, and (10) pediatric services.
Age adjustments vary between 1 (for 21-year-old buyers) and 3 (for 64-year-old buyers), with details for all ages shown in Figure 1.

This form of automatic age adjustment implies that — as long as age adjustment factors do not perfectly match age-differences in premiums that would result absent this regulation — base prices (hence premiums for all buyers) should vary with the composition of buyers in a market. For example, if buyers can only be 21 or 64-year-old, and the ratio between unconstrained premiums at 21 and 64 is, say, 1:5 (as approximately resulting from the Medical Expenditure Panel Survey, the pre-ACA data analyzed in Orsini and Tebaldi, 2015, and my own estimates in this paper) in response to the regulation premiums should be higher in markets with a higher share of 64-year-olds.

**Subsidies.** Although $P_{j\tau}^r$ is the premium received by the seller if a $\tau$-year-old buyer enrolls in plan $j$ in region $r$, subsidies are provided for all buyers whose household’s annual income is below four times the federal poverty level (FPL; approximately $47,000 in 2014). For this, the law establishes a cap on the premium amount each individual has to pay for the second-cheapest Silver plan (benchmark plan) in each region. This cap is a function of the individual’s household income (see Table 1), ranging from $684 for the lowest income group to $4,368 for the highest income group (among subsidized individuals). Importantly, given income this cap amount does not vary by age.

This defines a premium discount for each age ($\tau$) and income ($y$) in region $r$ equal to

\[
S^{\tau,y}(b_r) = \max \left\{ A^{\tau} \cdot b^*_r - P^y, 0 \right\},
\]

where $P^y$ is the premium cap for individuals with income $y$, and $b^*_r$ is the base price of the benchmark plan in the region. Since the law establishes that each buyer must pay at least $1, the price of plan $j$ for an individual with age $\tau$ and income $y$ in region $r$ is equal to

\[
P^{\tau,y}_{j\tau} = \max \left\{ P^{\tau}_{j\tau} - S^{\tau,y}(b_r), 1 \right\}.
\]

Figure 2 summarizes how age adjustments and subsidies transform base prices into prices faced by specific individuals, based on their age and income.

**Cost-sharing reductions.** A last important regulation in ACA exchanges is the provision of cost-sharing reductions, available for buyers purchasing a Silver plan and whose income is lower than 2.5 times the FPL. For them, the federal government covers part of deductible and out-of-pocket expenses, so that the actuarial value of Silver plans increases from 70% to approximately 87%.\footnote{Specifically, for income levels between 100-150% of the FPL the deductible is reduced to $0, and maximum out-of-pocket is $2,250; for income levels between 151-200% of the FPL the deductible increases to $550, and maximum out-of-pocket is also $2,250; while for income levels between 201-250% of the FPL the deductible is $1,850, and the }
Moreover, although the insurer covers approximately 70% of the health expenses, buyers’ utilization when enrolled in a Silver plan is as if the plan covered 87% of expenses, and therefore likely to be higher (c.f. “moral hazard” in health insurance, see e.g. Manning et al., 1987; Einav et al., 2013).

3.2 The case of Covered California

With its 1.4 million enrollees in 2014, the Californian exchange (Covered California) is the largest among ACA exchanges, and provides a useful setup to quantify the effect of alternative subsidy designs. The state is divided into 19 rating regions (see map in Figure 3), with the number of insurers active in each region varying between 3 and 6, for a total of 11 participants.

Strengthening federal regulations, in Covered California financial details of different levels of coverage are fully standardized (see Table 2), and when selling plans in a region each insurer must offer one plan in each level. Moreover, while the federal law allows some premium adjustments for tobacco use, these are not allowed in Covered California.

3.3 Data and summary statistics

My main data is an extract of the official records of Covered California, obtained via Public Records Act (CA Gov §6250). I combine this source with the 2012-2013 Area Health Resources File to construct the distribution of potential buyers across different age and income groups in the 19 Covered California rating regions. A detailed description of the original data files and of the construction of the final dataset can be found in Appendix B.

In every rating region \( r \) I observe the complete list of insurer-tier combinations \((j)\), and the corresponding base price \((b_{jr})\). The Covered California dataset contains 401 products (insurer-tier-region) and corresponding pricing decisions.

I also observe market shares by 6 age-income groups: combinations of age between 20-29, 30-44, and 45-64, and low-income subsidized (LI) or not (HI). For each age-income pair \((\tau, y)\), and each region \( r \), \( q_{jr}^{\tau,y} \) is the observed number of enrollees in plan \( j \), and \( G_r(\tau, y) \) is the number of potential buyers. The ratio \( s_{jr}^{\tau,y} = q_{jr}^{\tau,y}/G_r(\tau, y) \) is then the observed share of buyers choosing \( j \) conditional on the corresponding age-income group.

Knowing the ACA regulations on price adjustments, subsidies, and cost-sharing support, for each age-income pair and each product I then know the price paid by the buyer \( P_{jr}^{\tau,y} \), the price received by the insurer \( P_{jr}^{\tau,y} \), and product characteristics \( z_{yr}^{\tau,y} \) that are relevant for buyers’ decisions (see Table 2). Thus, corresponding to the 401 products and base prices — one pair for every

maximum out-of-pocket increases to $5,200.

10See http://ahrf.hrsa.gov/.

11To calculate subsidies and cost-sharing reductions I treat subsidized buyers as if their annual income was 200%
I observe a total of 2,160 combinations — one for every (region, insurer, tier, age, income) — of prices (for the buyer and for the seller), product’s characteristics, and market share within the specific age-income group.

**Prices across age and income.** Premiums that are relevant for buyers’ decisions are summarized in Table 3, which highlights the effect of age adjustments and subsidies.

Premiums for the high-income older than 45 are 3 times larger than those for high-income younger than 29. Because of the subsidy formula, however, this monotonicity does not hold for low-income buyers. For them, the subsidy design implies that Silver plans are available for approximately the same amount for all ages (the second cheapest Silver for exactly $1,452 for any age). For lower coverage, premiums decrease in age, while the opposite is true for Gold and Platinum plans, a pattern that is mechanically implied by (8) and (9), and can be seen directly in Figure 2.

**Market composition and subsidies.** The size and composition of potential buyers across the 19 regions — important for insurers’ pricing decisions and resulting enrollment — is summarized in Table 4. In terms of market size, the overall number of potential buyers varies from less than 34,000 for the easter region (Mono, Inyo, and Imperial counties) to approximately 1,000,000 in each of the two regions covering Los Angeles. Importantly, moreover, an average of 70% of potential buyers are eligible for ACA subsidies.

The age-income composition of the relevant population is also quite heterogeneous across regions, as already summarized in Table 4 but also depicted in Figure 4. For example, the San Francisco region has the minimum share of potential buyers older than 45 (36%), and a share of potential buyers eligible for subsidies of just 58%. At the opposite extreme, the northern region\(^{12}\) has maximum shares of both, over 45 (49%) and subsidy eligible (80%). As evident from Figure 4 many intermediate cases (rich and old, or poor and young regions) are also observed.

Given the ACA subsidy design, the price of the second-cheapest Silver plan for low-income buyers is fixed. However, as the base price of the benchmark plan varies across regions, the corresponding per-buyer transfer from the government to insurers also varies. As reported in Table 4, the base price of the benchmark plan is on average equal to $3,044, ranging from $2,338 to $3,690. This variation translates into a discount for a 21-year-old low-income buyer (paid to sellers directly by the government) equal to $1,592 in the average region, but this ranges from $886 to $2,238. For the oldest group of low-income buyers, the same variation in base prices of benchmark plans implies an average discount equal to $7,680, ranging from $5,562 to $9,618.

---

\(^{12}\)Region 1: Alpine, Amador, Butte, Calaveras, Colusa, Del Norte, Glenn, Humboldt, Lake, Lassen, Mendocino, Modoc, Nevada, Plumas, Shasta, Sierra, Siskiyou, Sutter, Tehama, Trinity, Tuolumne and Yuba counties.

\(^{13}\)Region 1: Alpine, Amador, Butte, Calaveras, Colusa, Del Norte, Glenn, Humboldt, Lake, Lassen, Mendocino, Modoc, Nevada, Plumas, Shasta, Sierra, Siskiyou, Sutter, Tehama, Trinity, Tuolumne and Yuba counties.
Enrollment and market structure. Given prices and market composition, to estimate demand I will use the corresponding purchase decisions across the 19 regions in the exchange. Average per-plan enrollment across age-income groups and different levels of coverage is summarized in Table 5. A first salient fact is that, due to the subsidies, participation among low-income buyers is higher than among high-income unsubsidized. While they are 70% of potential buyers, subsidy recipients make up for 88% of adult enrollment in Covered California.\footnote{My analysis and the main results are driven almost exclusively by estimates about this group, and – since my main focus is precisely on the subsidy program – little would change if I were to exclude the high-income unsubsidized. The exclusion of all children and young adults under the age of 20 is instead a significant limitation of my analysis, which might be resolved in the future as additional data are released.}

Additionally, the vast majority of these buyers chose either Bronze or Silver coverage. This concentration in plan selection can be largely explained by the availability of cost-sharing support, which makes Silver coverage comparable to Gold and Platinum while significantly cheaper.

Beside prices, population, and enrollment, another dimension of regional variation that I will exploit is variation in the combination of participating insurers and resulting distribution of market shares. The number of insurers goes from three to six, for a total of eleven participants. Four are large players — Anthem, Blue Shield, HealthNet, and Kaiser —, operating almost everywhere in the state. The remaining seven are smaller, local insurers offering coverage only in a small number of regions.

Insurers are differentially attractive in different regions and for different income groups, as I summarize in Table 6. Among the four largest carriers, each captures on average between 15-36% of subsidized buyers. Yet these shares range from a minimum of 10% to a maximum of 30% for HealthNet, 50% for Kaiser and Blue Shield, and over 90% for Anthem, the largest insurer in Covered California.

The comparison between market shares within subsidized to those within high-income buyers suggests that preferences for insurers may vary by income. For example, while Anthem has, on average, a share of high-income buyers of approximately 43%, within subsidized this drops to 36%. In contrast, a similar difference is “gained” in the opposite direction by Blue Shield, whose share within low-income, subsidized buyers is 6% higher than within high-income.

Part of these differences in the success of large insurers can be explained by the role played by small local insurers. For instance, Chinese Community Health Plan captures 33% of low-income buyers in San Francisco region 4, and 12% in San Mateo region 8; within high-income, however, this number drops to less than 7% in both regions. The opposite pattern is also observed, with Sharp — a local insurer in San Diego — enrolling 9% of low-income buyers, while 23% of buyers who pay their premiums in full.
4 Econometric model

The simple model introduced in section 2 is now extended, adapted to nest ACA regulations, and later combined with Covered California data to study the effect of different subsidy designs in this particular market.

4.1 Primitives

Markets, insurers, and products. There are $R$ geographic markets (regions), indexed by $r = 1, \ldots, R$. In each $r$, a population of individuals is offered $J$ health insurance plans by $N$ insurers, indexed by $n = 1, \ldots, N$. For each $n$, $J_n \subset J$ is the set of products offered by $n$, and with a slight abuse of notation $n(j)$ will denote the seller of product $j$.

Individual buyers. A potential buyer $i$ in region $r$ is defined by a tuple $(\tau^i, y^i, v^i, c^i)$; superscripts are used throughout to index buyers, while subscripts index regions, insurers, and products.

The pair $(\tau^i, y^i) \in T \times Y$ (both finite sets) denotes age and income of buyer $i$, and it is observed by all agents. Preferences of a buyer are instead unobserved by sellers, and are described by the vector $v^i = (v^i_1, \ldots, v^i_J) \in \mathbb{R}^J$. This collects $i$’s willingness to pay for each of the $J$ products relative to the outside option $j = 0$. For buyers of age-income $(\tau, y)$, $P^{\tau, y}_r = (P^{\tau, y}_{1r}, \ldots, P^{\tau, y}_{Jr})$ denotes the “price vector” of differences between the price of each $j$ and the price of the outside option (e.g. tax penalty for lack of insurance). Hence, $i$ chooses $j$ when $v^i \in D_j(P^{\tau^i, y^i}_r)$, where

$$D_j(P^{\tau^i, y^i}_r) = \left\{ v \in \mathbb{R}^J : \underset{k \in J}{\text{argmax}} \left\{ v_k - P^{\tau^i, y^i}_{kr} \right\} = j, \text{ and } v_j \geq P^{\tau^i, y^i}_{jr} \right\}. \quad (10)$$

Because it is not relevant to my analysis, I abstract away from how each $v^i$ could be derived from a more primitive model of choice under uncertainty (see Einav et al., 2013, for an example of this derivation with CARA preferences).

The last element characterizing $i$, $c^i = (c^i_1, \ldots, c^i_J) \in \mathbb{R}^J_+$, collects the costs that each insurer expects to bear if $i$ enrolls in a given product. That is, $c^i_j$ is equal to the amount that the seller of $j$ expects to spend to reimburse the health services of $i$ under insurance policy $j$ during the coverage period. Differences in $c^i_j$ across $j$ may reflect different underlying contracts with health providers, differences in administrative costs, differences in the generosity of coverage, or differences in expected utilization of health services.

Population. In every region, insurers’ share a common belief that age and income among potential buyers is distributed as $G_r(\tau, y)$, with $G_r(\tau, y) \geq 0$, and $\sum_{\tau, y} G_r(\tau, y) = 1$ for all $r$. Addition-

---

14Having an equal number of insurers and products across regions is a simplification to keep notation uncluttered, this does not affect the empirical application.
ally, insurers know that, conditional on a pair $(\tau, y)$, preferences and cost of buyers in region $r$ are distributed according to the continuous density $h_r(v^i, c^i | \tau, y)$.

Rather than the entire joint distribution $h_r$, the two relevant primitives that I will focus on throughout are the marginal density of preferences conditional on age and income:

$$f_r(v^i | \tau, y) = \int_{\mathbb{R}^J_+} h_r(v^i, c^i | \tau, y) \, dc^i,$$  \quad (11)

and the vector of expected costs for each $j$ in region $r$ conditional on age, income, and buyer’s preferences:

$$\psi_r(v, \tau, y) \equiv \int_{\mathbb{R}^J_+} c^i \cdot \frac{h_r(v, c^i | \tau, y)}{f_r(v | \tau, y)} \, dc^i.$$  \quad (12)

In words, $\psi_r(v, \tau, y)$ is the insurer’s expected cost when covering under plan $j$ a buyer with age-income $(\tau, y)$ and preferences $v$ in region $r$.

**Demand.** The function $\sigma_{jr}^{\tau,y}(P_r^{\tau,y})$ denotes the probability that a buyer with age-income $(\tau, y)$ purchases $j$ when the prices are $P_r^{\tau,y}$. Using the above notation this can be expressed as

$$\sigma_{jr}^{\tau,y}(P_r^{\tau,y}) \equiv \int_{D_j(P_r^{\tau,y})} f_r(v^i | \tau, y) \, dv^i.$$  \quad (13)

### 4.2 Regulations, profits, and equilibrium

Insurers do not adjust prices across age and income. Instead, for every product $j$, in region $r$ the seller chooses only a univariate base price $b_{jr}$. A regulation then determines both, the price paid by a buyer as function of age and income, and the price received by the seller as a function of age only.

Formally, $P_{jr}^{\tau} = R^\tau(b_{jr})$ is the revenue for the seller if a buyer of age $\tau$ purchases $j$. Of this amount, the buyer only pays the subsidized price $P_{jr}^{\tau,y} = P_{jr}^{\tau} - S^{\tau,y}(b_{jr})$, where the discount $S^{\tau,y}(b_{jr})$ is covered by the government, and it is computed via the subsidy formula (8) as a function of base prices in the region.

The expected profits for insurer $n$ in region $r$ are then a function of $b_r$:

$$\Pi_{nr}(b_r) = \sum_{j \in J_n} \sum_{\tau, y} G_r(\tau, y) \cdot \left( \sigma_{jr}^{\tau,y}(P_r^{\tau,y}) \cdot P_{jr}^{\tau} - \int_{D_j(P_r^{\tau,y})} \psi_{jr}(v^i, \tau, y) \cdot f_r(v^i | \tau, y) \, dv^i \right).$$  \quad (14)

With this as payoff function of the pricing game, base prices are set in each region as a Nash equilibrium, with each insurer maximizing $\Pi_{nr}(b_r)$ taking base prices of other insurers as given.\footnote{Since this is a model of imperfect competition between insurers offering vertically and horizontally differentiated products, insurers do not adjust prices across age and income. Instead, for every product $j$, in region $r$ the seller chooses only a univariate base price $b_{jr}$. A regulation then determines both, the price paid by a buyer as function of age and income, and the price received by the seller as a function of age only.}

**Demand.** The function $\sigma_{jr}^{\tau,y}(P_r^{\tau,y})$ denotes the probability that a buyer with age-income $(\tau, y)$ purchases $j$ when the prices are $P_r^{\tau,y}$. Using the above notation this can be expressed as

$$\sigma_{jr}^{\tau,y}(P_r^{\tau,y}) \equiv \int_{D_j(P_r^{\tau,y})} f_r(v^i | \tau, y) \, dv^i.$$  \quad (13)
5 Identification

A critical challenge for identification of the model’s primitives is that, differently from a market without selection, costs for insurers may not only vary by product, but also with the characteristics of the buyer. For this, my approach here relies on supplementing choice and price data with supply-side equilibrium assumptions, applying to this context the “inversion of first-order conditions” widely adopted by the industrial organization literature since Rosse (1970) and Bresnahan (1981). In terms of estimation, this idea is already present in Lustig (2010), but my main point here is to highlight sufficient conditions on observables that ensure that demand and cost functions are identified.

Observables. In every region, and for every product $j = \text{insurer-tier}$, observables consist of the collection
\[
\mathcal{O}_{jr} \equiv \left( b_{jr}, \left\{ P_{jr}^{\tau,y}, P_{jr}^s, s_{jr}^{\tau,y}, z_{jr}^y, G_r(\tau, y) \right\}_{\tau \in T, y \in Y} \right),
\]
along with functions $R^\tau(\cdot)$ and $S^{\tau,y}(\cdot)$ which determine price adjustments, and subsidies. Importantly, entry and product characteristics are fixed and exogenous throughout.

5.1 Overview of nonparametric identification

Nonparametric identification is formalized in Theorem 1 in Appendix C, but here I provide a brief summary before introducing a parametric version of the model and the corresponding identification argument that I use for estimation.

First, $f(\cdot|\tau, y)$ is identified for each age-income pair by inversion of the relationship between observed and model-predicted market shares: $s_{jr}^{\tau,y} = \sigma_{jr}^{\tau,y}(P_{jr}^{\tau,y})$. Sufficient conditions for this are provided by Berry and Haile (2014) (BH), and the essential requirement is observability of “price instruments” that do not directly affect choices, yet affect pricing decisions. In my model, base prices (and thus prices faced by buyers) depend on the population composition in terms of age and income, since this affects the shape of payoff functions in (14). If unobservables relevant for individual choices do not depend on population composition, the collection $\{G_r(\tau, y)\}_{\tau \in T, y \in Y}$ can be used as a set of valid price instruments (this is similar to Waldfogel, 2003). BH then show

plans, and the distribution of individual preferences and cost admits a continuous density, profit functions are continuous. This reduces concerns for lack of equilibrium existence emerging from discontinuity in payoffs, a first-order issue in models of insurance supply under perfect competition between vertically differentiated plans (see Handel, Hendel, and Whinston, 2015, for a rich discussion). An existence result in a model similar to mine is provided by Azevedo and Gottlieb (2014).

16 Identification of demand may also rely on different strategies, varying across contexts and data structures. For example, regression-discontinuity is used in Ericson and Starc (2015), while a mix of BLP-style instruments (other products’ characteristics, c.f. Berry, Levinsohn, and Pakes, 1995) and Hausman-style instruments (prices in different geographic markets) are used by Decarolis, Polyakova, and Ryan (2015). See also Berry and Haile (2015).
that if the support of prices (conditional on instruments) is sufficiently large, there exists a unique density $f_r(·|\tau, y)$ yielding $\sigma_{\tau,y}(\cdot)$ consistent with the observed market shares $s_{\tau,y}^r$.

Then, given that $\{f_r(·|\tau, y)\}_{\tau \in T, y \in Y}$ is identified, expected cost functions ($\psi_r$) are the remaining unknowns in the equilibrium FOC (here simplified to single-product sellers)

$$MR_{jr} = \sum_{\tau,y} G_r(\tau, y) \cdot \frac{\partial}{\partial b_{jr}} \left( \int_{D_j(P_{\tau,y}^r)} \psi_{jr}(v^i, \tau, y) \cdot f_r(v^i|\tau, y) \, dv^i \right),$$

where the left-hand side is equal to marginal revenues and does not depend on $\psi_r$. This is an underidentified system, with more unobserved unknowns than observed pricing decisions. Yet, leveraging on quasi-linearity of preferences, restrictions on how costs may vary across markets, and a constructive proof analogous to the one in Somaini (2011, 2015) yield sufficient conditions for identification of $\psi_r$. An essential requirement for this is that the same variation in prices used to identify demand induces variation in the composition of marginal buyers (in terms of $v, \tau,$ and $y$) across observed products.

### 5.2 Parametric identification using Covered California data

Sufficient conditions for identification hold under the following combination of parametric assumptions which I use for estimation using Covered California data.

**Demand.** Each individual $i$ with age-income $(\tau^i, y^i) = (\tau, y)$ has a (money-metric) indirect utility from purchasing $j$ in $r$ equal to

$$U_{jr}^i = -\alpha_{\tau,y}^r \cdot P_{jr}^r + (\beta_{\tau,y}^r) \cdot v^i_{\tau,y} + \delta_{\tau,y}^r + \xi_{jr} + \epsilon_{jr},$$

where $\epsilon_{jr}$ is iid distributed as a standard extreme value type I. $\xi_{jr}$ is instead the (endogenous) mean-zero error term capturing how unobserved characteristics of $j$ in region $r$ affect choice by buyers with age-income $(\tau, y)$.

The unknown parameters for every observed age-income combination are the price coefficient $\alpha_{\tau,y}^r$, the coefficients on product characteristics (deductible and out-of-pocket maximum) $\beta_{\tau,y}^r$, and insurers’ fixed-effects $\delta_{\tau,y}^r = (\delta_1^{\tau,y}, ..., \delta_N^{\tau,y})$.\(^\text{18}\)

---

\(^{17}\)Because preferences are quasi-linear in price, the set $D_j(P_{\tau,y}^r)$ is a cone in $\mathbb{R}^J$, and the set of marginal buyers of product $j$ in $r$ is the limit of an “L-shaped” set in $\mathbb{R}^J$ (limit for $\varepsilon \to 0$ of $D_j(P_{\tau,y}^r) \cap (\mathbb{R}^J \setminus D_j(P_{jr}^r, P_{jr}^r - \varepsilon))$). Somaini (2011, 2015) can then be followed to construct expected cost functions. (See Appendix C for details).

\(^{18}\)Estimates from alternative demand specifications including a random-coefficients model à la BLP (Berry, 1994; Berry, Levinsohn, and Pakes, 1995) are presented in Appendix D.
The standard inversion for multinomial logit discrete choice (see e.g. Berry, 1994) implies then that
\[ \sigma_{j,r}(P_{r}) = \exp\left(\mu_{j,r} + \xi_{j,r}\right) / \left(1 + \sum_{k \in I} \exp\left(\mu_{k,r} + \xi_{k,r}\right)\right), \]
and \( s_{j,r} = \sigma_{j,r}(P_{r}) \) yields to
\[ \xi_{j,r} = \ln(s_{j,r}) - \ln(s_{0,r}) - \mu_{j,r}. \] (18)

The parameters in (17) are identified if, next to standard rank conditions requiring population composition to shift prices conditional on insurer and product characteristics,\(^{19}\) for all \((\tau, y)\)
\[ E\left[\xi_{j,r} | z_{r}, \{G_{r}(\tau, y)\}_{\tau \in T, y \in Y}\right] = 0; \] (19)
requiring conditional mean independence between unobservables in the demand from a specific age-income group and population composition. Simply put, this assumes for example that unobservables (network of providers) affecting demand by 21-year-olds do not depend on the number of 64-year-olds in the same market.

If this is the case, since insurers’ profit functions (equation (14)) depend on the age-income composition of the region, variation in this composition as the one shown in Figure 4 can induce variation in observed base prices, which can then be used to identify demand. Figures 5 and 6 show that this variation is present in Covered California, highlighting the response of base prices (in natural logarithm) to variation in age-composition, and income-composition, respectively, after controlling for insurer and level of coverage fixed-effects.\(^{20}\) From Figure 5, the base price is higher in regions with a larger number of potential buyers older than 45. This is consistent with the ex-ante expected cost of covering old buyers being higher than three times the one of covering young buyers, and under the age rating regulations insurers set higher prices when relatively more buyers are over 45.\(^{21}\) Instead, as shown in Figure 6, regions with a higher percentage of subsidy-eligible buyers have lower prices. This is consistent with both, low-income buyers being more price sensitive, and with the market being larger (insurers are able to operate more efficiently, or pay lower rates to providers).

One possible concern with this approach is that insurers could have altered provider networks or marketing strategies taking into consideration market composition. If these features enter the error term \(\xi_{j,r}\), this would not be independent from \(\{G_{r}(\tau, y)\}_{\tau \in T, y \in Y}\), violating (19). To partially address this concern, in Appendix D I discuss robustness to an alternative strategy, where demand is estimated simultaneously across all age-income pairs with insurer-region fixed-effects. These fixed-

\(^{19}\)E \( [[z_{r}, \{G_{r}(\tau, y)\}_{\tau \in T, y \in Y}] [z_{r}, P_{r}] ] \) must be full-column rank.

\(^{20}\)I discuss first-stage estimates together with demand estimates in section 6.

\(^{21}\)In Orsini and Tebaldi (2015) we provide a pseudo placebo test for this, considering a large sample of counties across the entire US. While before the ACA there was no significant relationship between price of young buyers and number of old buyers in the county, this is now a positive and highly significant effect.
effects capture omitted characteristics which are constant across plans offered by the same carrier in a region, including provider networks. The remaining endogenous error $\xi_{jt}$ is then largely driven by functional form misspecification (e.g., differences in the money-metric valuation of provider networks across buyers of different age). From a practical perspective, this alternative approach yields similar estimates of the elasticities relevant for my final counterfactual.

Cost. Expected cost of coverage varies by age of buyer, tier of coverage, insurer, and region:

$$\psi_{jr}(\tau) = \phi^r + \phi_{\text{tier}} + \phi_{\text{n}(j)} + \phi_r.$$  \hfill (20)

Taking the estimated $\hat{\sigma}_{jr}^{\tau,y}(\cdot)$ as given, I then assume that base prices are set in equilibrium, and that insurers’ FOCs must hold up to a mean-zero error term. I interpret the source of this error as discrepancy between the population composition as assumed by insurers when setting base prices and the age-income composition $G_r$ as observed in my data.

Formally, $\hat{\eta}_{jr}$ is the value of marginal profits evaluated using the observed $G_r$:

$$\hat{\eta}_{jr} = \frac{\partial \hat{\Pi}_{n(j)r}(b_r)}{\partial b_{jr}} = \hat{MR}_{jr} - \hat{MC}_{jr}$$

$$= \hat{MR}_{jr} - \sum_{k \in J_{n(j)}} \sum_{\tau,y} G_r(\tau,y) \cdot \frac{\partial \hat{\sigma}_{kr}^{\tau,y}}{\partial b_{jr}} \cdot \psi_{kr}(\tau),$$ \hfill (21)

where marginal revenues $\hat{MR}_{jr}$ are constructed from demand estimates and base prices applying age rating and subsidies. As long as the difference between the observed $G_r$ and the population composition assumed by insurers is independent from agents’ choices,

$$E \left[ \hat{\eta}_{jr} \bigg| z_r, b_r, s_r \right] = 0,$$ \hfill (22)

where conditioning variables exclude the population composition $G_r$ which is correlated with $\hat{\eta}_{jr}$.

Identification of tier, insurer, and region parameters of the individual cost function (20) is standard, relying on variation of marginal revenues (equal to cost) across tiers, insurers, and regions, respectively. Instead, identification of cost differences for the same product across different buyers is peculiar to my context, and in general to selection markets.

For this, parametric restrictions such those in (20) are needed, since otherwise the number of unknowns is larger than the number of observed pricing decisions.\footnote{This differs from the case of standard consumption goods, where assuming equilibrium pricing one identifies marginal cost nonparametrically for every observed product without additional assumptions (see e.g. Bresnahan, 1981; Berry, Levinsohn, and Pakes, 1995; Berry and Haile, 2014).} Moreover, as it is evident from
equation (21), insurers’ risk-neutrality implies that marginal profits are linear in expected costs across buyers of different age, and this delivers the condition for identification of $\phi^\tau$.

Specifically, to distinguish cost differences between two age-groups $\tau, \tau'$, the composition of marginal buyers across the two groups must vary across observed products, requiring variation in the ratio

$$\frac{\text{marginal buyers of age-income } \tau, y}{\text{marginal buyers of age-income } \tau', y} = \frac{G_r(\tau, y) \cdot \partial \hat{\sigma}^\tau_{kr, y} / \partial b_{jr}}{G_r(\tau', y) \cdot \partial \hat{\sigma}^\tau'_{kr, y} / \partial b_{jr}}.$$  \hspace{1cm} (23)

This is a special case of the more general result presented in Appendix C, and the main intuition is summarized with an abstract example in Figure 7, in which I consider two age groups, over and under 45.

Demand estimates and population composition can be used to calculate per-buyer marginal revenues (vertical axis), and percentage of marginal buyers younger than 45 (horizontal axis). This can be done for every observed product (panel (A)), assuming that cross-insurer, cross-tier, and cross-region differences have been controlled for. The co-variation between marginal revenues and composition of marginal buyers is observed, but can also be predicted by the model for any given pair of parameters $\phi^{20-44}$ and $\phi^{45-64}$ (panel (B)). This follows the linear relationship:

$$\hat{MR}_{jr} = \hat{MC}_{jr} = (\text{under 45 marginal buyers}) \cdot \phi^{20-44} + (\text{over 45 marginal buyers}) \cdot \phi^{45-64}. \hspace{1cm} (24)$$

As long as the age-composition of marginal buyers varies, there exists a unique pair of cost parameters $\hat{\phi}^{20-44}$ and $\hat{\phi}^{45-64}$ for which the model-predicted marginal cost is (in expectation) equal to the one implied by demand estimates and equilibrium pricing conditions (panel (C)).

6 Estimates from Covered California data

6.1 Demand by age and income

First-stage: population composition and base prices. Estimated coefficients from a hedonic regression of base prices on product characteristics and age-income composition are reported in Table 7. As anticipated, the effect of population composition on pricing decision is large in size and highly significant. Looking at specifications in levels and natural logarithms, the Share 45-64 and Share 100-400% FPL – both excluded from individual demand equations – explain approximately 20% of the variation in base prices across markets.

After controlling for insurer and contract details, the base price of a plan increases by 8.3% (+$243 per year) if the share of over 45 among potential buyers increases by 10%. The share of subsidy eligible buyers also matters: a 10% increase in the size of this group relative to all potential buyers induces an estimated drop in base price of 6.6% (−$205 per year).
Demand estimates. Demand estimates across the six age-income groups in Covered California data are obtained exploiting this variation in prices, as well as cross-market differences in the set of participating insurers.

Coefficients from equation (17) are reported in Table 8, and are obtained correcting for endogeneity of $P_{jr}^{y}$ using a control function. This is convenient here because the subsidy design implies that the level of prices of low-income buyers is maintained approximately constant (at least for the second cheapest Silver plan) at $1,452. Therefore, the instruments vary mostly the dispersion of prices for subsidized buyers around this value. With a control function, however, I can exploit the rating regulations and capture unobservables affecting rating decisions by adding to the indirect utility the residuals of the hedonic regression in the first stage. Robustness to different specifications and methods to correct for endogeneity of premiums — including standard 2SLS estimates and the specification with insurer-region fixed-effects discussed in the previous section — is presented in Appendix D. These alternative strategies yield very similar elasticity estimates.

The bottom rows of Table 8 report averages of (age-income specific) own-price elasticities (% drop in plan enrollment if the annual premium increases by 1%), and extensive margin semi-elasticities (% drop in overall coverage in the region if all prices increase by $100).

Commenting on the results: Preferences for insurance are estimated to be quite heterogeneous across different age groups, and between subsidized and unsubsidized buyers. Magnitudes of the estimated coefficients on annual premium are decreasing in income and age, and, more relevantly, implied own-price elasticities go from $-3\%$ for the 20-44 low-income people, to $-1.5\%$ for 45-64 low-income. This value drops to $-1\%$ (approximately constant in age) among the high-income.

Extensive margin semi-elasticities are also highly heterogeneous. If all premiums increase by $100, approximately 12\% of buyers who are subsidized and whose age is between 20-44 would opt out of Covered California. Instead, for the over 45 subsidized, a uniform $100 increase in all prices would reduce participation by less than 4\%. The same extensive margin is even smaller among high-income unsubsidized.

Beside price, also the estimated effect of product characteristics on buyers’ choices are consistent with intuition: buyers like lower deductible and lower out-of-pocket expenditure. In particular, comparing the two more demanded contracts in Covered California, a low-income younger than 30 would be willing to pay, on average, an additional $1,000 to be covered under a Silver plan ($550 deductible and $2,250 maximum out-of-pocket) rather than under a Bronze plan ($5,000 deductible and $6,250 maximum out-of-pocket). For the same increase in coverage, a low-income buyer older than 45 would be willing to pay more than $2,500, showing again significant age-heterogeneity in the valuations of different contracts.

\footnote{For this discussion I focus on low-income buyers since estimates for the unsubsidized group are much less precise, and not relevant for my results. These represent the minority (less than 10\%) of buyers in the Covered California data, and are not directly affected by the subsidy program which I will alter in the counterfactual.}
Lastly, insurers’ fixed-effects are aligned with differences in market shares already highlighted in Table 6. Anthem is the most preferred, followed closely by Blue Shield, Kaiser, and HealthNet. When active, certain local insurers are comparable to the four large players (e.g. Chinese Community Health plan, Sharp, or Valley), although this is not the case for all participants, with Contra Costa, Molina, LA Care, and Valley estimated to be inferior for all buyers.

6.2 Expected cost by age, tier, insurer, region

Variation in composition of marginal buyers. In Figure 8 I reproduce using Covered California data and demand estimates the illustration of cost identification in Figure 7 (section 5.2). I plot the co-variation between estimated marginal revenues and age composition of marginal buyers. I exploit this variation to estimate cost, varying by buyer’s age, contract details, insurer, and region.

As shown in the figure, the larger the fraction of under 45 buyers among those reacting to changes in $b_{jr}$, the lower the individual marginal revenue predicted by the demand model, equal to cost under my equilibrium assumption. At the same time, more generous plans (left vs. right panel for, respectively, Silver vs. Gold coverage) have a higher marginal revenue/cost, and – as highlighted with different symbols – after controlling for level of coverage and age composition of marginal buyers regional differences directly impact how cost estimates vary in different regions. (A similar intuition holds for differences between insurers.)

Cost estimates. Driven by this variation, cost estimates are obtained imposing the moment condition (22), and reported in Table 9. Columns (1)-(3) show estimates allowing only for product, insurer, and region heterogeneity, as in a model without selection. Then, in columns (4)-(6) the same specifications are estimated allowing expected costs to vary also by age. For this, I distinguish between over and under 45-year-old, and use only the products that are available to all buyers (Bronze, Silver, Gold, and Platinum).24

Estimated expected cost increases in generosity of coverage and age. Looking at the more comprehensive specification in column (6) – which I will also use for my counterfactuals – to enroll a young buyer in a Bronze plan ($5,000 deductible and $6,250 out-of-pocket maximum) costs Anthem approximately zero in expectation ($200, not statistically significant). For the same plan the carrier expects instead to spend on average $5,860 if the buyer is older than 45.

As coverage increases, expected cost increases as well. Enrolling a buyer in a Silver plan costs the insurer $1,600 if the buyer is under 45, and over $7,000 if older. This is the contract chosen by the vast majority of subsidized buyers (see Table 5), hence these estimates are the most important.

24 This choice is dictated by the necessity of observing sufficient variation in composition of marginal buyers across products (after conditioning on insurer and market averages). In the Covered California data, subsidized buyers are the most price sensitive, and make up for 90% of enrollment. Moreover, buyers younger than 45 have very similar preferences, so that the main variation in composition of marginal buyers and enrollment pools relevant for pricing decisions is variation in the relative share of under 45 among marginal buyers, and this is what I focus on.
for my final results, and the more robust across different specifications.\textsuperscript{25} This implies a cost-ratio of approximately 4.5 between the two groups, so that age rating restrictions yield to higher prices for young buyers than what they would be charged if age-based price discrimination was unrestricted.\textsuperscript{26}

The second relevant dimension of cost-heterogeneity is across insurers. Anthem and Blue Shield of California are estimated to have almost identical cost. For HealthNet, instead, I estimate a lower individual cost (by $500, only significant at the 20\% level), while for Kaiser Permanente a higher cost ($600, highly significant). This is driven by differences in prices and/or estimated attractiveness. Kaiser, in particular, has higher prices in most markets, and differences in elasticity do not alone explain these price differences. Hence the model rationalizes higher prices with a higher average cost for the carrier.\textsuperscript{27}

Lastly, regional effects are also relevant to cost, and are jointly significant at any conventional level.\textsuperscript{28} Moreover, inspecting how estimates vary across different markets, I find that cost tend to be lower in urban areas, and particularly in regions with a high number of health providers per-capita.\textsuperscript{29} This is in line with the fact that cost of specific procedures when covered by the insurer varies with the structure of the market of health providers (see also Ho, 2009; Ho and Lee, 2013).

\textsuperscript{25}Importantly, for Silver plans expected cost for the insurer is driven by two factors. First, insurers expect buyers to behave as if deductible and co-pays were lower because of cost-sharing reductions, and this may affect their utilization. Given utilization, however, the insurer expects claims to reflect a contract with a $2,250 deductible and $6,250 out-of-pocket (the difference is paid for by the government).

\textsuperscript{26}In Orsini and Tebaldi (2015) we also show that, before the ACA, the ratio of unrestricted prices of identical products between 64 and 21 was equal to 4.023. Similar numbers are obtained using the Medical Expenditure Panel Survey as shown in Appendix D.

\textsuperscript{27}This fact might be surprising, as this large integrated HMO is known for providing high quality health services while able to contain its cost. The difference in prices has been explained in various, alternative ways, which I briefly discuss here although to take a specific stand favoring one explanation over the other is beyond my purpose. First of all, Kaiser’s vertical integration implies that its marginal cost might include more “cost items” than those considered by a non-integrated insurer, for which individual cost is mostly driven by expected utilization and negotiated reimbursements to physicians (also see Ho and Lee, 2013). Moreover, in the public discussion it has been highlighted how Kaiser has capacity constraints, and so its strategy to post high-prices in ACA exchanges might in fact be a way to limit the influx of new patients into its hospitals and clinics during the first years after the reform. Lastly, Kaiser’s official position is that its providers’ networks were not adjusted ad-hoc to the new regulations, while other insurers allegedly selected a small set of their providers to be covered by plans offered in Covered California. (See http://articles.latimes.com/2013/jun/12/business/la-fi-kaiser-health-rates-20130613)

\textsuperscript{28}I can only consider the joint significant of these estimates, as I do not assume independence across plans within a given market. Thus, the variance on each individual market fixed-effect cannot be estimated.

\textsuperscript{29}For example, Los Angeles county, San Francisco, and Alameda, where according to the Dartmouth Atlas (http://www.dartmouthatlas.org/) there are approximately 3 (acute care) hospital beds per-1,000 residents, insurers’ expected cost is estimated to be lower than in San Mateo, or in the Eastern region, where hospital beds per-1,000 residents are less than 2.
7 Equilibrium under different subsidy designs

Building on the model adopted thus far, and using estimates from Covered California, I can now compare equilibrium under different designs of the subsidy program.

7.1 Vouchers vs. price-linked discounts

My first comparison is between the ACA subsidy design and an “equivalent” voucher program, where buyers receive fixed discounts equal to those resulting in equilibrium under the current scheme.

To start, recall that under the ACA design if base prices are $b_{r}^{ACA}$ buyers receive price-linked discounts $S_{r}^{y}(b_{r}^{ACA})$ computed via equation (8). I compare this to the alternative design $\hat{S}$, under which buyers receive a fixed discount (“equivalent voucher”) $\hat{S}_{r}^{y} = S_{r}^{y}(b_{r}^{ACA})$, which is not adjusted as insurers’ pricing decisions $b_{r}$ vary. Because young buyers are more price-sensitive and cheaper to cover, insurers’ marginal profit functions under $\hat{S}$ lay below marginal profit functions under $S$ (discussion in section 2 and Appendix A). Therefore, even in this richer model insurers set lower base prices under the voucher scheme $\hat{S}$ than under the ACA design, and relevant equilibrium quantities respond accordingly.

To quantify these differences I start off by computing equilibrium base prices $b_{r}^{ACA}$ under the status quo subsidy design. For this, I use demand and cost estimates from Covered California, and assume that insurers use the observed age-income composition $G_{r}$ to compute expected profits in each region.30 I then carry on the same equilibrium computation under the equivalent voucher scheme $\hat{S}$ and compare the two equilibria in terms of enrollment by age group, average cost, average markups (difference between total per-person amount received by the insurer and average cost), and subsidy expenditure.

Table 10 reports the results of this comparison, showing that differences between the two designs are indeed sizable. In particular, under fixed vouchers equilibrium markups are 15% lower (approximately $200 per-year) and coverage is higher than under the ACA design. This is driven by insurers setting lower base prices, yielding to lower pre-discount premiums.

At these lower premiums, because vouchers are not adjusted discounted prices are lower than under the ACA design, and enrollment is higher (+7% among under 45, and +9% for the older group). With these changes in enrollment the age-composition of buyers remains almost unaltered (+1%), and this reflects into average cost being approximately the same in the two equilibria. Markups reductions are then largely explained by a lower per-person amount received by insurers, combination of lower average subsidy provided by the government (−5%), and lower contribution paid by buyers (−11%).

30In practice, I find base prices that solve the equilibrium FOC precisely, rather than with the error $\hat{\eta}_{jr}$. 
7.2 Age-adjusted vouchers

Next I quantify the difference in equilibrium outcomes induced by variations in the voucher amount across different age groups; this allows me to explore the potential gains from age-targeted subsidies. I consider fixed vouchers analogous to \( \hat{S} \), where instead of setting voucher values equal to the discounts provided under the ACA scheme, for any age group \( \tau \) there is an amount \( V^\tau > 0 \) for which \( \hat{S}^\tau = V^\tau \). (I omit \( y \) from the notation since I observe only one income level in my data.)

The discussion in Section 2 highlights that, within this class of subsidy schemes, reducing vouchers for the old and increasing those for the young can yield to lower average cost, higher coverage, and lower per-buyer spending. Intuitively, increasing the relative share of young buyers in enrollment pools lowers average cost and markups (by raising average elasticities), thus induces insurers to set lower prices. If this price reduction exceeds the amount by which the voucher of the older group was raised, all buyers are better off.

To investigate this mechanism, I simulate and report equilibrium outcomes for different pairs of voucher values \( (V^{20-44}, V^{45-64}) \), varying these over a two-dimensional grid of $100 increments. In Figure 9 I plot level curves (in the space of voucher values) for equilibrium outcomes that would likely enter the government’s objective: average cost, average premium received by insurers, enrollment for different age groups, and subsidy expenditure (both per-insured person and aggregate). To facilitate comparisons, for each outcome I highlight the curve corresponding to the equilibrium level under the ACA design, and each other curve corresponds to a 10% increase (or decrease) from this level.

Interpreting the figure, panel (c) and (d) show how equilibrium enrollment in the two age groups varies as a function of vouchers. Because they are less price sensitive, for old buyers level curves of enrollment are significantly sparser than those of the young, corresponding to a flatter surface. In practice, a $100 increase in \( V^{20-44} \) yields to a much larger increase in enrollment among the young than the drop in enrollment among the old implied by a $100 reduction in \( V^{45-64} \).

One can then increase \( V^{20-44} \), reduce \( V^{45-64} \), and obtain higher coverage for both groups, with lower cost, lower premiums, and lower per-person public spending. The effect of age adjustments to vouchers follows, as it is shown directly by the downward sloping curves in panel (d): one can increase \( V^{20-44} \), reduce \( V^{45-64} \), and obtain higher coverage for both groups, with lower cost (panel (a)) and lower per-person public spending (panel (e)).

In Table 11 I compare with more precision equilibrium outcomes along two level curves depicted in panel (d), with voucher values for which enrollment of the over 45 is approximately constant at either 1.08 or 1.02 times the equilibrium level under the ACA. In both situations a $400 increase in \( V^{20-44} \) and a simultaneous $200 reduction \( V^{45-64} \) maintain enrollment of the older group approximately invariant. At the same time, however, enrollment among under 45 increases by approximately 60%, and average cost is 10-15% lower. Since young buyers are more price-sensitive
markups are also lowered, up to a 25% drop from ACA levels (approximately $448 per-person-year), and per-person public expenditure is reduced by more than 15% (or $600 per-person-year).

7.3 ACA price-linked discounts with age-specific price caps

My results thus far suggest that the use of age-adjusted vouchers might be preferable to the current ACA scheme (price-linked discounts not tailored by age). However, price-linked discounts have the important advantage of ensuring the final price for the buyer. The government needs to know less about the determinants of insurers’ and buyers’ decisions, and can avoid the risk of setting vouchers that are either too high or too low. Nevertheless, even if only price-linked discounts are feasible, age adjustments might still be desirable due to age-heterogeneity in demand and cost.

In my last counterfactual I consider this, comparing the ACA scheme (where price caps used to compute discounts are equal to $1,400 for all ages) to a scheme with price-linked discounts but with premium caps varying by age. Practically, I consider a scheme \( \hat{S} \) such that

\[
\hat{S}^{\tau,y}(b_r) = \max\{A^{\tau} \cdot b^*_r - P^{\tau,y}, 0\},
\]

in which \( P_{20-44,y} < P_{45-64,y} \), and \( b^*_r \) is the second-cheapest base price of Silver plans in the region. This is then the same scheme \( S \) as implemented under the ACA (equation (8)), with the only difference being that price caps vary also by age (under \( S \) one has \( P_{20-44,y} = P_{45-64,y} = P^y \)). Practically, one can also think of this as a scenario in which the government provides — on top of the current subsidy program — additional incentives for the participation of young buyers with different fiscal instruments.

The results of this comparison are reported in Table 12, where I show how equilibrium outcomes respond to progressively lower price caps for the under 45. Higher generosity of the subsidy scheme for young buyers yields again to large increases in their participation, and a corresponding reduction in average cost and per-buyer subsidy outlays. Yet, gains relative to the ACA scheme are smaller than under age-adjusted vouchers, since markup reductions are lower (from over 20% to less than 10%), a consequence of the additional distortions induced by price-linked discounts.

7.4 Summary of equilibrium comparative statics under different designs

I summarize the above comparisons in Figure 10, where I express differences between the ACA design and possible alternatives in head-counts (for enrollment) and dollars (for average cost, markup, and subsidy).

The figure highlights the different role played by the two aspects of subsidy design that I focused on. On the one hand, using vouchers instead of price-linked subsidies increases price competition, and thus lowers markups and the cost for the government of covering a low-income buyer. On the other hand, tailoring discounted prices to age does not imply a redistributive trade-off, but rather
is a powerful tool to affect the market average cost, insurers’ markups, and per-buyer government expenditure. Importantly, the two mechanisms co-exist and either complement or offset each other under different design alternatives.

8 Conclusions

The recent changes to the US health care system, primarily induced by the 2010 national reform, opened many questions for regulators and economists. Within the growing body of work on regulation of private insurance, in this paper I used an empirically tractable model of imperfect competition between insurers to study (static) equilibrium under different designs of the ACA subsidy program.

The applied contribution is two-folded. First, I estimated the model in the post-reform status quo, regulated by the ACA and in which the vast majority of buyers are low-income and thus subsidy eligible. Second, my counterfactuals highlighted that the ACA subsidy scheme leaves room for possible improvements that are quantitatively significant and consistent with theoretical predictions. Additionally, from a methodological perspective, I formalized sufficient conditions to identify (unobserved) cost primitives in a selection market, relying on the combination of equilibrium assumptions with the variation in prices and choices exploited to identify demand.

In my application I used data from the first year of operations of the Californian exchange to obtain estimates of demand and cost. Importantly, the buyers in this market belong to a segment of the population that was largely underrepresented in previous studies, and I found a large degree of heterogeneity (both in demand and cost) across buyers of different age.

These estimates are the drivers of my counterfactual results. Price-linked subsidies as mandated by the ACA increase insurers’ market power, implying higher markups, lower coverage, and higher spending when compared to a mechanism where low-income discounts are not adjusted to prices. I quantified this distortion to be approximately $200 per-person-year (15%). A second result is that age-adjustments of subsidized premiums within a given income level might lead to better outcomes, both in terms of enrollment levels and efficiency in the use of public funds. This alternative might be easier to implement than exogenous vouchers, and the gains follow directly from the heterogeneity in cost across buyers: Raising the participation of “young invincibles” generates a positive externality on the entire market, reducing costs, prices, and the public spending for every insured buyer. Supporting intuition, my simulations suggested that potential gains are sizable: One can maintain enrollment among buyers who are older than 45 approximately unaltered, increase enrollment among younger buyer by more than 50%, while reducing per-insured public spending by $600 per-year. With the government intent to increase coverage while limiting spending, a modification of the subsidy scheme to allow for age-specific premium even among low-income buyers could then improve upon the current regulation.
Looking at ACA exchanges, here I focused on the design of the subsidy program, with a partial equilibrium analysis that holds other parts of the regulations unchanged. Subsidies are indeed only one piece of the large regulatory innovation mandated by the reform, and different rules complement each other in generating market outcomes. Versions of the model I employed here could also be used to study other ACA regulations, such as age-rating restrictions, cost-sharing support, risk-adjustment mechanisms, or tax-penalties for the uninsured.

Dynamic incentives of buyers — e.g. choice inertia — and insurers — e.g. entry and network-setting decisions — could also play a relevant role in determining outcomes in this market. As the exchanges enter their third year of operations (during fall 2015), in the future it will be possible to use richer models and data to account for these additional dimensions. It is somewhat comforting for my analysis — and necessary in order to take seriously my cost estimates and counterfactuals — is that the Californian market has been a very stable environment thus far: Prices and market shares of individual plans did not vary significantly from year one to year two, and no relevant entry or exit episodes occurred.\(^{31,32}\) Moreover, recently released data on statewide average per-enrollee claims incurred in 2014 by Anthem Blue Cross — the largest insurer in Covered California — confirmed that my cost estimates matched closely the realized cost of this carrier.\(^{33}\) This also provides evidence that the use of supply-side first-order conditions to estimate sellers’ costs is a viable approach in selection markets for which claims data are not available.

Although sensible, my results are obtained using limited data from the first year of this new market, and the study of the design of the ACA and other government-sponsored insurance programs remains challenging. This defines a rich agenda for future work using multiple years of prices and enrollment, detailed information on networks of providers and utilization, individual-level demographics matched to plan choice, or detailed claims information, which could lead to more precise estimates of relevant primitives and quantifications of the corresponding policy implications.

References

---

\(^{31}\) The autocorrelation in plan-level base prices between 2014 and 2015 was 0.98, while the autocorrelation in plan-level market shares between 2014 and 2015 was 0.96. No entry occurred, and the only insurer leaving the exchange in 2015 was Contra Costa, the smallest insurer in 2014 with less than 1,000 enrollees.

\(^{32}\) My modeling assumptions would be harder to justify for those states that in the early years of the ACA exchanges saw significant churn in prices, market shares, and insurers’ participation decisions.

\(^{33}\) The average yearly incurred claim filed by Anthem was $4,632, I estimated an expected average cost for Anthem equal to $4,616. See https://www.cms.gov/CCIIO/Resources/Data-Resources/ratereview.html.

APPENDIX

Appendix A. Comparative static of alternative subsidy designs

A1. Derivation of equilibrium condition (5)

Given a subsidy design $S$, rewrite the profit function for product $j$ as

$$
\Pi_j^S (P_j, P_{-j}) = Q_j^S (P_j, P_{-j}) (P_j - AC_j^S (P_j, P_{-j})) ,
$$

(26)

where $AC_j^S (\cdot)$ is defined in (3) and $Q_j^S (P) = G(Y) \sigma_j (P - S (P, Y), Y) + G(O) \sigma_j (P - S (P, O), O)$.

If $P^*$ is an equilibrium one has

$$
\frac{\partial \Pi_j (P_j^*, P_{-j}^*)}{\partial P_j} = \frac{\partial Q_j^S (P_j^*, P_{-j}^*)}{\partial P_j} (P_j^* - AC_j^S (P_j^*, P_{-j}^*)) + Q_j^S (P_j^*, P_{-j}^*) \left( 1 - \frac{\partial AC_j^S (P_j^*, P_{-j}^*)}{\partial P_j} \right) = 0;
$$

and rearranging terms leads to

$$
P_j^* = AC_j^S (P_j^*, P_{-j}^*) - Q_j^S (P_j^*, P_{-j}^*) \left( 1 - \frac{\partial AC_j^S (P_j^*, P_{-j}^*)}{\partial P_j} \right).
$$

(27)

To simplify this further, rewrite

$$
- \frac{Q_j^S (P_j^*, P_{-j}^*)}{\partial Q_j^S (P_j^*, P_{-j}^*)} = \frac{Q_j^S (P_j^*, P_{-j}^*)}{G(Y) \sigma_j (P^* - S (P^*, Y), Y) \eta_{jj}^Y + G(Y) \sigma_j (P^* - S (P^*, O), O) \eta_{jj}^O}
$$

$$
= \frac{1}{\alpha_j^S (P^*) \eta_{jj}^Y + (1 - \alpha_j^S (P^*)) \eta_{jj}^O};
$$

(27)

$$
\frac{\partial AC_j^S (P_j^*, P_{-j}^*)}{\partial P_j} = (C_j^Y - C_j^O) \frac{\partial \alpha_j^S (P^*)}{\partial P_j} =
$$

$$
= (C_j^Y - C_j^O) \frac{\partial(G(Y) \sigma_j (P^* - S (P^*, Y), Y)) Q_j^S (P^*)}{\partial P_j} - G(Y) \sigma_j (P^* - S (P^*, Y), Y) \frac{\partial Q_j^S (P^*)}{\partial P_j}
$$

$$
= (C_j^Y - C_j^O) (\eta_{jj}^O - \eta_{jj}^Y) \alpha_j^S (P^*) (1 - \alpha_j^S (P^*)) .
$$

(28)
Putting together (27) and (28) gives the expression for the equilibrium price in (5):

\[ P_j^* = AC_j^S(P_j^*, P_{j, S}^*) + \frac{1 - \left( C_j^Y - C_j^O \right) \left( \eta_{ijj}^O - \eta_{ijj}^Y \right) \alpha_j^S(P^*) \left( 1 - \alpha_j^S(P^*) \right)}{\alpha_j^S(P^*) \eta_{ijj}^Y + \left( 1 - \alpha_j^S(P^*) \right) \eta_{ijj}^O} \]  \hspace{1cm} (29)

A2. Equilibrium comparative static

Before introducing two propositions formalizing the discussion in Section 2, for any subsidy design \( S \) let \( g^S \) be the corresponding per-insured public spending in equilibrium:

\[ g^S = \frac{G(Y) \sigma_j \left( P_j^*, S \left( P_j^*, S, Y \right), Y \right) S \left( P_j^*, S \right) + G(O) \sigma_j \left( P_j^*, S - S \left( P_j^*, O \right), O \right) S \left( P_j^*, O \right)}{G(Y) \sigma_j \left( P_j^*, S - S \left( P_j^*, Y \right), Y \right) + G(O) \sigma_j \left( P_j^*, S - S \left( P_j^*, O \right), O \right)} \]  \hspace{1cm} (30)

**Targeted vs. non-targeted subsidies.** The first proposition states that a voucher that is more generous for the low-cost, high-elasticity group leads to lower prices than a non-targeted voucher. Moreover, if the price reduction is sufficiently large, all buyers are better-off and the government spends less.

**Proposition 1** If prices are strategic complements and \( C_j^Y < C_j^O \), \( \eta_{ijj}^Y > \eta_{ijj}^O \) for all \( j \):

(a) if \( S \) is a non-targeted voucher scheme \( S \left( P, \tau \right) = V \), for which, at the equilibrium prices \( P_j^*, S \), \( \alpha_j^S(P_j^*, S) < \frac{1}{2} \) for all \( j \), then there exists a \( \Delta > 0 \) such that, for the targeted voucher scheme \( \hat{S}(P,Y) = V + \Delta, \hat{S}(P,O) = V - \Delta, P_j^*, \hat{S} < P_j^*, S \);

(b) if, moreover, \( P_j^*, S - P_j^*, \hat{S} > \Delta \) for all \( j \), then equilibrium quantities purchased under \( \hat{S} \) are higher in both groups, and \( g^\hat{S} < g^S \).

**Proof.** I prove part (a), and part (b) follows immediately by simple algebra.

For all \( P \), \( \alpha_j^S(P) < \alpha_j^S(P) \), and since \( C_j^Y < C_j^O \), \( AC_j^S(P) < AC_j^S(P) \). Moreover, since \( \eta_{ijj}^Y > \eta_{ijj}^O \), the denominator in \( MK_j^S(P) \) is smaller than the denominator in \( MK_j^S(P) \).

Then, if for some \( \Delta > 0 \), the numerator in \( MK_j^S(P) \) is larger than the numerator in \( MK_j^S(P) \) — at least in a neighborhood of \( P_j^*, S \) —, then the right-hand side of (5) is lower under \( \hat{S} \) than under \( S \), and since prices are strategic complements Vives (1990) implies \( P_j^*, \hat{S} < P_j^*, S \).

To obtain the result it is then sufficient to consider the equilibrium point \( P_j^*, S \), and setting \( \alpha_j^S(\Delta) \equiv \alpha_j^S(P_j^*, S) \) check that the function

\[ \Phi_j(\Delta) = 1 - \left( C_j^Y - C_j^O \right) \left( \eta_{ijj}^O - \eta_{ijj}^Y \right) \alpha_j^S(\Delta) \left( 1 - \alpha_j^S(\Delta) \right) \]
is decreasing in $\Delta \in [0, \bar{\Delta}]$ for some $\bar{\Delta} > 0$. Since $\tilde{\alpha}^*,S(0) < \frac{1}{2}$, $\frac{d\tilde{\alpha}^*,S(0)}{d\Delta} > 0$, one has

$$\Phi'_j(0) = - (C_j^Y - C_j^O) (\eta_{jj} - \eta_{jj}^Y) \frac{d\tilde{\alpha}^*,S(0)}{d\Delta} < 0,$$

and the result follows. ■

**Price-linked discounts vs. vouchers.** The second proposition shows that, as long as there is a group of buyers who are more price sensitive and cheaper to cover, given price-linked subsidies it is possible to find a voucher scheme leading to an equilibrium with lower prices.

**Proposition 2** Assume that prices are strategic complements, and let $S$ be a subsidy design for which at any $P$, $\frac{\partial S(P, \tau)}{\partial P_j} = \delta > 0$, for some $j$ (which may depend on $P$). Then, if $C_j^Y < C_j^O$, and $\eta_{0j}^Y > \eta_{0j}^O$ for all $j$, a voucher scheme $\hat{S}$ such that $\hat{S}(P, \tau) = \hat{V} = S(P^*,S, \tau)$ is such that $P^* < P^*,S$.

**Proof.** From the equilibrium comparative static results formalized in Vives (1990), the proof amounts to show that, for all $P$ at which all products make weakly positive profits, setting $\hat{S}(P, \tau) = \hat{V} = S(P, \tau)$ implies

$$\frac{\partial \Pi_j^S(P_j, P_{-j})}{\partial P_j} \geq \frac{\partial \Pi_j^{\hat{S}}(P_j, P_{-j})}{\partial P_j} \text{ for all } j, \tag{31}$$

with a strict inequality for at least one $j$. (This immediately implies that $\frac{\partial \Pi_j^{\hat{S}}(P^*,S)}{\partial P_j} < 0$ for at least one $j$: At the equilibrium prices under $S$, if the vouchers $\hat{S}$ are adopted, at least one insurer wants to lower its price).

To show (31), given that at prices $P$ for at least one $j$, $\frac{\partial S(P, \tau)}{\partial P_j} = \delta > 0$, and for all $k$, $P_k \geq AC^S_k(P)$, one has that for any $j$:

$$\frac{\partial \Pi_j^S(P_j, P_{-j})}{\partial P_j} - \frac{\partial \Pi_j^{\hat{S}}(P_j, P_{-j})}{\partial P_j} \geq \delta \left( \frac{\partial Q_j^S(P)}{\partial P_0} (P_j - AC_j^S(P_j, P_{-j})) - Q_j^S(P) \frac{\partial AC_j^S(P)}{\partial P_0} \right)$$

$$= \delta \left( P_j - AC_j^S(P_j, P_{-j}) - \frac{Q_j^S(P)}{\frac{\partial Q_j^S(P)}{\partial P_0}} \frac{\partial AC_j^S(P)}{\partial P_0} \right) > 0.$$
Hence (31) follows if \( \frac{\partial AC_j^S(P)}{\partial P_0} < 0 \): raising the price of the outside good (or equivalently the subsidy) lowers average cost. This is indeed the case as long as \( C^Y_j < C^O_j \), and \( \eta^Y_0j > \eta^O_0j \):

\[
\frac{\partial AC_j^S(P)}{\partial P_0} = \left( C^Y_j - C^O_j \right) \frac{\partial \alpha_j^S(P)}{\partial P_0} = \left( C^Y_j - C^O_j \right) \left( \frac{\partial G(Y) \sigma_j(P - S(Y), Y)}{\partial P_0} \right) \frac{\partial Q_j^S(P)}{P_0} = \left( C^Y_j - C^O_j \right) \left( \eta^Y_0j - \eta^O_0j \right) (1 - \alpha_j^S(P)) < 0.
\]

Therefore (31) holds and, by Vives (1990), \( P^*, \hat{S} < P^*, S \).

Appendix B. Details of data construction

B1. Enrollment by age and income

In 2014, Covered California provided me with total enrollment \( Q_{jr} \) for every product \( j \) (insurer-tier pair) in every region \( r \), for a total of \( N = 401 \) products in the exchange.

Additionally, the exchange published for every income \( y = LI, HI \), and every region \( r \):

- \( \Pr[\tau, y|r] \): the share of buyers of age \( \tau \), \( \tau \in \{[20, 29], [30, 44], [45, 64]\} \), and income \( y \) in region \( r \);
- \( \Pr[n, y|r] \): the share of income \( y \) buyers of plans sold by insurer \( n \), in region \( r \);
- \( \Pr[x, y|r] \): the share of income \( y \) buyers of plans in tier \( x \), in region \( r \).

Therefore, since \( j = (n, x) \), I impute the enrollment \( q_{j}^{\tau, y} \) of product \( j \) in region \( r \) restricted to the age-income group \( (\tau, y) \) via Bayes rule:

\[
q_{j}^{\tau, y} = Q_{jr} \cdot \Pr[\tau, y|j, r], \quad \Pr[\tau, y|j, r] = \Pr[\tau, y|n, x, r] = \frac{\Pr[\tau, y, n, x|r]}{\Pr[n, x|r]} = \frac{\Pr[n, y|r] \Pr[x, y|r] \Pr[r, y|r]}{\Pr[n, x|r]},
\]

where

\[
\Pr[n, x|r] = \Pr[j|r] = \frac{Q_{jr}}{\sum_k Q_{kr}}.
\]

This assumes that conditional on income, tier choice does not depend on the specific insurer, and that both tier and insurer choice do not depend on age.

Importantly, more granular data released in October 2015 (after the second open enrollment, see http://hbex.coveredca.com/data-research/) confirmed that the market shares conditional on age and income resulting from this construction match very closely the choices taken by buyers in the first two years of the exchange. This data could later be incorporated in my analysis.
B2. Market composition

The 2012-2013 Area Health Resources file (http://ahrf.hrsa.gov/) contains, for every county $c$ in the US, the following variables:

- $U^\tau_c$: number of uninsured individuals of a given age $\tau$, $\tau \in \{[20, 29], [30, 44], [45, 64]\}$;
- $H^y_c$: number of households with income $y$, $y \in \{[0, 10k), [10k, 15k), [15k, 25k), [25k, 50k), [50k, 100k), [100k, \infty)\}$.

Since subsidy eligibility for a family of two starts at $16,000$, and stops at $70,000$, I approximate the share of uninsured of a given age $\tau$ and income $y = LI, HI$ in county $c$ as

$$G_c(\tau, LI) = \frac{U^\tau_c \sum_{y \in [15k, 100k]} H^y_c}{\sum_{\tau'} U^{\tau'}_c \sum_{y \in [15k, \infty)} H^y_c}, \quad (35)$$

$$G_c(\tau, HI) = \frac{U^\tau_c \left( 1 - \frac{\sum_{y \in [15k, 100k]} H^y_c}{\sum_{y \in [15k, \infty)} H^y_c} \right)}{\sum_{\tau'} U^{\tau'}_c}. \quad (36)$$

Then, if $C(r)$ is the set of counties in region $r$, the share of age-income $(\tau, y)$ potential buyers is calculated as the following population-weighted average:

$$G_r(\tau, y) = \frac{\sum_{c \in C(r)} U_c G_c(\tau, y)}{\sum_{c \in C(x)} U_c}, \quad (37)$$

where $U_c = \sum_{\tau} U^\tau_c$.

I obtain similar results when using alternative constructions based on the PUF file of the Californian Health Insurance Survey (http://healthpolicy.ucla.edu/chis/Pages/default.aspx), or using exchange estimates of the subsidy eligible in each region before the first open enrollment period.

The latter source displays a similar cross-region variation but significantly smaller overall market size. As a result, in several regions enrollment during the first year was greater than the predicted number of eligible buyers, and since then the exchange removed these predictions from the web. Yet, omitting the regions with negative share of the outside good, demand estimates using this source to determine potential buyers remain similar to the ones in my baseline specification.

Since the income composition measured here does not correspond exactly with subsidy eligibility under the ACA, in one robustness check in Appendix D I inflate or deflate the overall market size in each region by up to 40%, and demand estimates across age-groups are not substantially different. In fact, what is relevant for the validity of my results is that my construction captures correctly the cross-region variation in age-income shares, rather than the exact size of each market.
Appendix C. Nonparametric identification

In this appendix I provide conditions for nonparametric identification of the distribution of willingness to pay and of cost conditional on willingness to pay, assuming that observables consists of choices, prices, and products’ characteristics.\(^{34}\)

For this I use a model that is not tailored to my specific application, omitting subsidies and other regulations. This allows me to focus on, and highlight, the novel aspect of the identification argument, which is to use equilibrium assumptions and variation in the preferences of marginal buyers to identify cross-buyer cost heterogeneity. I provide a positive result for the case of single-plan insurers (or plan-level pricing decisions), an important simplification that leaves open questions for future work. In fact, multi-product pricing decisions introduce several complications, with the need of additional conditions, a different constructive proof, or specific functional form assumptions (e.g. those in the empirical application in this paper, or in Lustig, 2010).

C1. Model and observables

I start by adopting the model of demand used in Berry and Haile (2014) (BH), and then model supply allowing costs to vary with buyers’ willingness to pay, and assuming that a Nash-in-prices equilibrium realizes in each market.

Demand (adapted from BH). Each consumer \(i\) in market \(r\) chooses a plan (or product) from a set \(J = \{0, 1, \ldots, J\}\). A market consists of a continuum of consumers in the same choice environment (e.g. geographic region). Formally a market \(r\) for the \(J\) products is a tuple \(\chi_r = (x_r, p_r, \xi_r)\), collecting characteristics of the products or of the market itself. Observed exogenous characteristics are represented by \(x_r = (x_{1r}, \ldots, x_{Jr})\), where each \(x_{jr} \in \mathbb{R}^K\). The vector \(\xi_r = (\xi_{1r}, \ldots, \xi_{Jr})\), with \(\xi_{jr} \in \mathbb{R}\), represents unobservables at the level of the product-market. Finally, \(p_r = (p_{1r}, \ldots, p_{Jr})\), with each \(p_{jr} \in \mathbb{R}\), represents (endogenous) prices.

Consumer preferences are represented with a random utility model quasilinear in prices (Section 4.2 in BH). Consumer \(i\) in market \(r\) derives (indirect) utility \(u_{jr}^i = v_{jr}^i - p_{jr}\) when purchasing \(j\), with the usual normalization \(v_{0r}^i = 0\), for all \(i\), all \(r\). Given prices, the choice of each buyer is then determined by the vector \(v_r^i = (v_{1r}^i, \ldots, v_{Jr}^i)\). For each buyer in market \(r\), \(v_r^i\) is drawn i.i.d. from a continuous density \(f_r(v)\). This satisfies the following:

D1. BH Demand structure: There is a partition of \(x_{jr}\) into \((x_{jr}^{(1)}, x_{jr}^{(2)})\), where \(x_{jr}^{(1)} \in \mathbb{R}\), such that given indexes \(\delta_r = (\delta_{1r}, \ldots, \delta_{Jr})\), with \(\delta_{jr} = x_{jr}^{(1)} + \xi_{jr}\), \(f_r(v) = f(v|\delta_r, x_{jr}^{(2)})\).

\(^{34}\)This is the main difference between my approach and existing work on identification of demand and cost in selection markets, where the observability of costs (e.g. ex-post claims) has been assumed (c.f. Einav, Finkelstein, and Cullen, 2010a; Bundorf, Levin, and Mahoney, 2012, and many others). One exception is Lustig (2010), who like me estimates costs using equilibrium pricing conditions. While our estimators are similar, my point here is to formalize which variation is sufficient for identification.

39
Therefore, assuming that \( \arg \max_{j \in J} u^i_{jr} \) is unique with probability one in all markets, choice probabilities (market shares) are defined by

\[
s_{jr} = \sigma_j(\chi_r) = \int_{D_j(p_r)} f(v|\delta_r, x_r^{(2)}) \, dv, \quad j = 0, 1, \ldots, J,\]

(38)

\[
\mathcal{D}_j(p_r) = \{ v : v_j - v_k \geq p_j - p_k, \text{ for all } k \neq j \}.\]

(39)

**Observables.** Let \( z_r = (z_{1r}, \ldots, z_{Jr}) \), \( z_{jr} \in \mathbb{R}^J \), denote a vector of cost shifters excluded from the demand model. The econometrician observes \((p_{jr}, s_{jr}, x_{jr}, z_{jr})\) for all \( r \) and all \( j = 1, 2, \ldots, J \).

**Supply.** Let \( w_{jr} = (\xi_{jr}, x_{jr}, z_{jr}) \in \mathbb{R}^{K+L+1} \) collect characteristics (observable and unobservable) and cost shifters of product \( j \) in \( r \). When purchasing \( j \), a buyer \( i \) with valuations \( v^i = v \) in market \( r \) increases the total expected cost for the insurer by \( \psi_j(v, w_{jr}) \), \( \psi_j: \mathbb{R}^J \times \mathbb{R}^{K+L+1} \to \mathbb{R} \).

The function \( \psi_j(\cdot, w_{jr}) \) is continuous and bounded for all \( j \), and describes how the expected cost of covering the buyer varies with her vector of valuations after conditioning on \( w_{jr} \).

At the prices \( p_r \) the seller of \( j \) realizes profits in market \( r \) equal to

\[
\Pi_{jr}(\chi_r) = p_{jr} \cdot \sigma_j(\chi_r) - \int_{D_j(p_r)} \psi_j(v, w_{jr}) \cdot f(v|\delta_r, x_r^{(2)}) \, dv.\]

(40)

I assume that in each market prices are set in a complete information Nash equilibrium in pure-strategies. To formalize this, the set of marginal buyers of product \( j \) can be described by

\[
\partial\mathcal{D}_j(p_r) = \{ v : v_j - v_k = p_{jr} - p_{kr}, \text{ for some } k \neq j \} \quad (41)

\[
= \lim_{\varepsilon \downarrow 0} \{ D_j(p_r) \cap (\mathbb{R}^J \setminus D_j(p_{jr} + \varepsilon, p_{-jr})) \}.\]

(42)

Then, following Uryas’ev (1994); Weyl and Veiga (2014), quasilinearity of indirect utility with respect to price implies that, in equilibrium, in every market \( r \):

**S1. Equilibrium:** For all \( j = 1, \ldots, J \), \( mr_{jr} = mc_{jr} \), where

\[
mr_{jr} = \sigma_j(\chi_r) - p_{jr} \cdot \int_{\partial\mathcal{D}_j(p_r)} f(v|\delta_r, x_r^{(2)}) \, dv,\]

(43)

\[
mc_{jr} = -\int_{\partial\mathcal{D}_j(p_r)} \psi_j(v, w_{jr}) \cdot f(v|\delta_r, x_r^{(2)}) \, dv.\]

(44)

From S1, marginal revenues are equal to marginal costs, which must be true in a Nash-in-prices equilibrium. The integrals in \( mr_{jr} \) and \( mc_{jr} \) are well defined because \( f(\cdot|\delta_r, x_r^{(2)}) \) and \( \psi_j(\cdot, w_{jr}) \) are both continuous and bounded functions of \( v \).

---

35As in section 4, \( \psi \) and \( f(v) \) could be derived from a more primitive joint distribution \( h(v, c) \) over individual preferences and cost, as shown in equations (11) and (12). If this joint distribution admits a continuous density, the resulting \( \psi_j \) is continuous in \( v \), which here is a maintained assumption.
C2. Conditions for identification

Identification is defined as in Roehrig (1988); Matzkin (2008): if the unobservables differ (almost surely), then the distribution of observables differ (almost surely), where probabilities and expectations are defined with respect to the distribution of \((\chi_r, s_r, z_r)\) across markets.

My result is obtained combining conditions for identification of demand provided in BH — yielding to identification of \(\xi_r\) and then of \(f(v|\delta_r, x_r^{(2)})\) — with a constructive proof to identify \(\psi_j\) which I adapted from Somaini (2011, 2015). To simplify notation without loss of generality, as in BH I condition on \(x_r^{(2)}\) — which unlike \(x_r^{(1)}\) can affect the distribution of preferences quite arbitrarily — and suppress it.

Beside the demand and supply assumptions D1 and S1, I will use the following conditions:

C1. BH Exogeneity of cost shifters: For all \(j = 1, \ldots, J\), \(E[\xi_{jr}|z_r, x_r] = E[\xi_{jr}] = 0\).

C2. BH Completeness: For all functions \(B(s_r, p_r)\) with finite expectations, if \(E[B(s_r, p_r)|z_r, x_r] = 0\) with probability one, then \(B(s_r, p_r) = 0\) with probability one.

C3. Large support: For every \(j\), \(\text{supp} \ v_r|\delta_r, w_{jr} \subset \text{supp} \ p_r|\delta_r, w_{jr} \subset P\), with \(P\) bounded.

Condition C1 is a standard exclusion restriction, requiring mean independence between demand instruments and the structural errors \(\xi_{jr}\). Condition C2 is a completeness assumption, requiring instruments to move market shares and prices sufficiently to distinguish between different functions of these variables through the exogenous variation in these instruments. C3 is a large support assumption, requiring cost shifters excluded from \(\psi_j\) to move prices in a set that covers the support of (conditional) valuations. This is a stronger requirement than the large support assumption sufficient to identify the distributions \(f(v|\delta_r)\), which would only require \(\text{supp} \ v_r|\delta_r \subset \text{supp} \ p_r|\delta_r\). The stronger condition in C3 allows to prove that cost functions \(\psi_j\) are also identified.

One then has:

**Theorem 1** Under D1, S1, C1, C2, C3, \(\xi_r\), \(f(v|\delta_r)\), and \(\psi_j\) are identified.

**Proof of Theorem 1.** Condition C3 implies that \(\text{supp} \ v_r|\delta_r \subset \text{supp} \ p_r|\delta_r\), and demand is identified using:

**Lemma 1** (Berry and Haile, 2014) Under D1, C1, C2, \(\xi_r\) is identified, and \(f(v|\delta_r)\) is also identified if, additionally, \(\text{supp} \ v_r|\delta_r \subset \text{supp} \ p_r|\delta_r\).

**Proof.** Follows from Theorem 1 and Section 4.2 in BH. □

---

36 This highlights the parallelism between auctions with interdependent costs and selection markets. In the former case (expected) marginal costs depend on the competitors’ signals, varying with differences of bids between competitors. In a selection market (expected) marginal costs depend on the preferences of buyers choosing the plan, varying with differences of prices between competitors.
Similarly to Somaini (2011, 2015), the rest of the proof amounts to approximating for every \( j \), every \( w_{jr} \), and every \( \hat{v} \in \text{supp } v_r|\delta_r, w_{jr} \), the integral of cost conditional on \( D_j(\hat{v}) \):

\[
\Psi_j(\hat{v}; w_{jr}, \delta_r) = \int_{D_j(\hat{v})} \psi_j(v, w_{jr}) \cdot f(v|\delta_r) \, dv. \tag{45}
\]

The mixed-partial \( J-1 \) derivative with respect to \( \hat{v}_{-j} \) yields then identification of the unknown cost function \( \psi_j \), since

\[
\frac{d^{J-1}\Psi_j(\hat{v}; w_{jr}, \delta_r)}{d\hat{v}_{-j}} = \psi_j(\hat{v}, w_{jr}) \cdot f(\hat{v}|\delta_r) \tag{46}
\]

and \( f(\hat{v}|\delta_r) \) is identified by Lemma 1. This exploits the fact that price enters linearly in buyers’ indirect utility, hence the set \( D_j(\hat{v}) \) is described by a set of inequalities which defines a cone in \( \mathbb{R}^J \) with vertex \( \hat{v} \). The boundary of this cone is the set \( \partial D_j(\hat{v}) \) defined in (41); see also Figure 1 in BH.

To approximate \( \Psi_j(\hat{v}; w_{jr}, \delta_r) \), fix \( j \), \( w_{jr} \), and \( \hat{v} \in \text{supp } v_r|\delta_r, w_{jr} \). Consider then a parametric curve \( \eta : \mathbb{R}_+ \to \mathbb{R} \), with \( \eta(\ell) = \hat{v}_j + \ell \), and with this define the function

\[
\hat{\Psi}_j(\ell) = \Psi_j(\eta(\ell), \hat{v}_{-j}; w_{jr}, \delta_r). \tag{47}
\]

Differentiating \( \hat{\Psi}_j(\ell) \) (and using again Uryas’ev, 1994; Weyl and Veiga, 2014) yields

\[
\frac{d\hat{\Psi}_j(\ell)}{d\ell} = -\int_{\partial D_j(\eta(\ell), \hat{v}_{-j})} \psi_j(v, w_{jr}) \cdot f(v|\delta_r) \, dv. \tag{48}
\]

The function \( \phi_j(\ell) \equiv \frac{d\hat{\Psi}_j(\ell)}{d\ell} \) is bounded and continuous, and hence Riemann integrable over \([0, T] \), where by C3 the upper bound \( T \) can be chosen to be such that \( \hat{\Psi}_j(T) = 0 \). Therefore,

\[
\Psi_j(\hat{v}; w_{jr}, \delta_r) = \hat{\Psi}_j(0) = -\int_0^T \phi_j(\ell) \, d\ell. \tag{49}
\]

The integral in (49) can be approximated with arbitrary precision. For this, one can choose a sequence \( \{\ell^n\}_{n=0}^N \) for which \( 0 = \ell^1 < \ell^2 < \ldots < \ell^{N-1} < \ell^N = T \), and using C3 build a corresponding sequence \( \{\chi^n_r\}_{n=0}^N \in \text{supp } \chi_r|\delta_r, w_{jr} \), such that \( p^n_r = (\eta(\ell^n), \hat{v}_{-j}) \). Then, as \( \max_n\{\ell^n - \ell^{n-1}\} \) becomes arbitrarily small

\[
\sum_{n=0}^{N-1} \phi_j(\ell^n)(\ell^{n+1} - \ell^n) \approx \int_0^T \phi_j(\ell) \, d\ell, \tag{50}
\]

where by all the elements in the Riemann sum are identified since by S1 each \( \phi_j(\ell^n) \) can be replaced by

\[
mv^n_{jr} = \sigma_j(\chi^n_r) - p^n_{jr} \cdot \int_{\partial D_j(\eta_r)} f(v|\delta^n_r) \, dv, \tag{51}
\]

which is identified by Lemma 1. ■
D Robustness and consistency with external cost data

D1. Robustness of price elasticities of demand to different specifications

Table 13 reports average own-price elasticity by age groups (for low-income buyers) using different demand specifications:

- In column (1) I report elasticities from the baseline specification, corresponding to the last row of Table 8;
- In column (2) I report elasticities from the same specification, where instead of a control-function I use a standard 2SLS logit-demand for every age-income observed in the data;
- In column (3) I report elasticities obtained from a mixed-logit as in Berry, Levinsohn, and Pakes (1995), with random coefficients on price with age-income specific mean. The indirect utility from purchasing $j$ in $r$ for a buyer $i$ with age-income $(\tau, y)$ is
  \[
  U_{ijr} = -(\alpha^i + \alpha^{\tau,y}) \cdot P^{\tau,y}_{ijr} + (\beta^{\tau,y})' z^y_{ijr} + \delta^{\tau,y}_{n(j)} + \xi^{\tau,y}_{ijr} + \epsilon^i_{ijr},
  \]  
  where $\alpha^i \sim N(0, \sigma^{\tau,y})$, and as in the baseline model $\epsilon^i_{ijr}$ is iid distributed as a standard extreme value type I. The estimated $\sigma^{\tau,y}$ is negligible.
- In column (4) I report elasticities obtained from the joint-estimation (N=2,160) of the six demand system (one for every age-income) via simple OLS with insurer-region-income fixed effects and restricting the coefficients on deductible and out-of-pocket limits to vary only by income. This is meant to capture the unobserved network of providers, varying across regions for the same insurers, but equal within a given insurer-region pair. Formally the specification is:
  \[
  U_{ijr} = -(\alpha^\tau + \alpha^y) \cdot P^{\tau,y}_{ijr} + (\beta^y)' z^y_{ijr} + \delta^y_{n(j)} + \delta^{\tau,y}_{n(j)} + \epsilon^i_{ijr}.
  \]  
- In column (5) I report elasticities (coefficient estimates) obtained from a log-quantity on log-price 2SLS regression, a specification that departs from the multinomial choice model:
  \[
  \ln(q^{\tau,y}_{ijr}) = -(\alpha^y + \alpha^\tau) \cdot \ln(P^{\tau,y}_{ijr}) + (\beta^y)' z^y_{ijr} + \delta^y_{n(j)} + \delta^{\tau,y} + \gamma \ln(M_r) + \nu^{\tau,y}_{ijr},
  \]  
  where the instruments for $\alpha^y$ and $\alpha^\tau$ are the age-income composition of the region, and $M_r$ is the total number of potential buyers in the market.
- In columns (6)-(7) I report elasticities from the baseline specification where I deflate (inflate) the total number of potential buyers in all regions — constructed with error from the Area Health Resources file — by 40%.
D2. External cost data

In the figure below I report a comparison between my cost estimates — obtained assuming equilibrium pricing and using the demand estimates from Covered California — to the distribution of annual health expenditure by age in the Medical Expenditure Panel Survey.

To be more specific, using the survey I regress 2011 annual health expenditure (sum of insured claims and individual contributions) of privately insured buyers between 20-64, with income lower than $44,000, on age fixed-effects. These are plotted with the corresponding 95% confidence intervals, and compared to my cost estimates for the average $0 deductible, Platinum plan.
FIGURES AND TABLES

Figure 1: Age adjustment factors in ACA exchanges

Note: Age adjustment factors under the ACA. For every age $\tau$, the line in the figure shows the corresponding factor $A^\tau$, which is used to compute the price of a high-income, unsubsidized buyer (equation (7)). If the base price of the product is $b_{jr}$, $P_{jr}^\tau = A^\tau \cdot b_{jr}$. This is also equal to the total amount that the insurer receives when a subsidized buyer purchases the plan. This curve was suggested by the Center for Medicare and Medicaid Services, and adopted by 48 states, including California. See also Orsini and Tebaldi (2015).
Figure 2: Transformation of base price in premium according to ACA regulations.

(a) Silver

(b) Non-Silver

Figure 2 summarizes the transformation of base price in the price paid by 21 and 64-year-old, unsubsidized and subsidized with income at 200% of the FPL.

As the figure highlights, these transformations are different for Silver and non-Silver plans. The second-lowest base price of Silver plans is in fact used to determine subsidies, ensuring that the price paid by the buyer is lower than the price cap as determined by the law (panel (a)). This determines the size of the discounts, which are then applied to all plans (vertical distance between dashed and solid lines in panel (b)).

Note: In both panels: second lowest Silver = $2,000, lowest Silver = $1,600, price cap = $1,300.
The map shows the 19 rating regions in Covered California. In each region, every spring insurers can announce their participation in the following year’s open enrollment. The exchange needs to authorize entry, and requires the insurer to offer five coverage levels with pre-determined financial characteristics (Table 2). In the summer insurers set one base price for every level of coverage in every region where they entered, prices and subsidies are then calculated from base prices applying ACA regulations (Section 3).
Figure 4: Share over 45 and Share subsidy eligible across regions in Covered California

Note: Each point in the scatter is a rating region in Covered California, with the region number inside the circle. Six regions, including the three main metropolitan areas of Los Angeles (LA), San Francisco (SF), and San Diego (SD), are labeled. This shows the variation in the instruments which exploited to estimate demand. Because of rating regulations and subsidies, insurers set different base prices in markets with different age-income composition. Assuming that unobservables affecting individual choice do not depend on market composition, variation in prices across regions in this scatter, and the corresponding change in market shares, are used to estimate demand parameters.
Figure 5: First-stage: base prices vs. share of over 45

OLS residuals of
\[
\log(b_{jr}) = \text{insurer fixed-effect} + \text{tier fixed-effect}
\]
plotted against the share of over 45 in the region, one graph for each coverage level

Note: Each panel contains, for the corresponding tier of coverage, the scatter plot of (x-axis) the share of potential buyers older than 45 in the region, and corresponding (y-axis) OLS residuals from the hedonic regression of (log) base prices in Covered California on insurer and tier fixed-effect; N=401.

Identification of demand elasticities in the baseline specification uses the variation highlighted in the figure as source of regional variation in prices, maintaining the assumption that the unobserved age-income specific error $\xi_{jr}^{x,y}$ in equation (17) does not depend on the share of 45 or older in the market.
Figure 6: First-stage: base prices vs. share subsidy eligible

OLS residuals of

$$\log(b_{jr}) = \text{insurer fixed-effect} + \text{tier fixed-effect}$$

plotted against the share of subsidy eligible in the region, one graph for each coverage level.

Note: Each panel contains, for the corresponding tier of coverage, the scatter plot of (x-axis) the share of potential buyers who are subsidy eligible, and corresponding (y-axis) OLS residuals from the hedonic regression of (log) base prices in Covered California on insurer and tier fixed-effect; N=401.

Identification of demand elasticities in the baseline specification uses the variation highlighted in the figure as source of regional variation in prices, maintaining the assumption that the unobserved age-income specific error $$\xi_{jr,y}$$ in equation (17) does not depend on the share of subsidy eligible in the market.
Figure 7: Intuition for identification of differences in expected cost across age

(A)

(B)

(C)

The figure illustrates an abstract of how variation in the composition of marginal buyers is used to identify cost differences across age. After estimating demand, and controlling for insurer and market differences, I consider the empirical relationship between per-buyer marginal revenues – in equilibrium equal to marginal cost – and the share of marginal buyers younger than 45 (panel (A)). For any pair of parameters $\phi^{20-44}$ and $\phi^{45-64}$ the model also implies a relationship between marginal revenues/cost and share of under 45 (panel (B)). Panel (C) shows a combination of $\hat{\phi}^{20-44}$ and $\hat{\phi}^{45-64}$ for which the model-predicted variation corresponds to the one inferred from demand estimates.
Figure 8: Individual marginal revenue/cost and composition of marginal buyers

For Silver (left panel) and Gold (right panels) plans, the figure plots the relationship between average per-buyer marginal revenue predicted by the demand model (on the y-axis) and share of marginal buyers younger than 45 (x-axis); each point (or symbol) corresponds to an insurer-region pair in Covered California in the corresponding tier. Different symbols are used for the three urban areas of Los Angeles, San Francisco, and San Diego. This exemplifies the variation I use to obtain cost estimates after assuming equilibrium, and thus that marginal revenues on the y-axis are equal to marginal cost: The slope of the linear fits leads to the estimated heterogeneity across ages (see also Figure 7), the vertical distance between the two lines to the variation in contract details, and the variation between regions to the market-fixed effects.
The figure shows level curves of equilibrium outcomes resulting under an age-adjusted voucher as functions of the voucher for the under 45 (x-axis) and voucher for the over 45 (y-axis). The level corresponding to the baseline ACA equilibrium (model fit) is highlighted in red, and every level curve corresponds to a 10% increase (decrease) for that level. The graph is obtained simulating equilibrium base prices — zeroing first-order conditions — as vouchers value vary over the grid in $100 increments.
The figure summarizes the comparison between the ACA subsidy design and the three alternatives I consider in my counterfactuals: fixed vouchers with amounts equivalent to the discounts in the equilibrium under the ACA — black bars —, age-adjusted vouchers chosen to be such that over 45 enrollment is 3% higher than under the ACA — crosshatched bars —, and age-adjusted price-linked discounts where the price ceiling on Silver coverage for the under 45 is raised to have the same enrollment as under age-adjusted vouchers — shaded bars. The bars are derived from Tables 10, 11, and 12.
Table 1: Price caps for subsidy calculation in ACA exchanges, different levels of income

<table>
<thead>
<tr>
<th>Income as % of FPL</th>

<td>Price cap of 2\textit{nd} cheapest Silver</td>
<td>$684</td>
<td>$1,452</td>
<td>$2,416</td>
<td>$4,368</td>
</tr>
</tbody>
</table>

Note: The table shows, as a function of a buyer’s income, the maximum amount that can be spent on the second cheapest Silver plan in the region. For each age-income pair, the subsidy is computed as the difference between the premium of this product (after age adjustment) and the corresponding share of annual income for the buyer. The bottom row shows the corresponding price cap on monthly price for the second cheapest Silver plan in the region.

Note: Control function logit demand regressions for each (age, income) group. Robust standard errors in parentheses. Bold coefficients are significant at the 1% level, italics coefficients are significant at the 10% level. The second to last row reports the average of implied product-level own-price elasticity (% drop in enrollment in the plan if the premium increases by 1%). The bottom row reports the average of implied region-level extensive margin, showing the % change in overall enrollment in Covered California plans if all prices for the (age, income) in the region increase by $100.

F-stat on market FE: 55.943 (p-value) <0.0001  98.193 (p-value) <0.0001

Note: The table reports the estimates of average per-buyer expected costs for different specifications of equation (20). Columns (1)-(3) estimate cost varying only by contract type, seller, and region, but constant across buyers. Columns (4)-(6) allow cost to vary also by age. Standard errors are block-bootstrapped drawing regions, and repeating the entire 2-step estimation procedure; 200 draws. The F-statistic on the market fixed effects tests the null hypothesis that these are all equal to zero.
Table 10: Comparison between ACA price-linked discount and vouchers

<table>
<thead>

</tr>
</tbody>
</table>

Note: Market outcomes in the simulated equilibrium under the ACA (fit of baseline model) and relative change in these outcomes in the equilibrium under a voucher program that provides, in every region, discounts equal to those resulting in equilibrium under the ACA. The average “equivalent” voucher is $1,500 for the under 45 and $6,500 for the over 45.

</tbody>
</table>

Note: Market outcomes (relative to the ACA equilibrium in the baseline model) in the simulated equilibrium under alternative pairs of age-adjusted vouchers. Both panels show market outcomes changing as the voucher for the under 45 is raised and the voucher for the over 45 is lowered. The top panel corresponds to a level curve of over 45 enrollment equal to 102-103% of the ACA level, while the bottom panel corresponds to a level curve of over 45 enrollment equal to 107-110% of the ACA level; see also Figure 9.

<td>0.86</td>
<td>0.90</td>
</tr>
</tbody>
</table>

Note: Market outcomes (relative to the ACA equilibrium in the baseline model) in the simulated equilibrium under alternative pairs of age-adjusted price-linked subsidies. The table shows market outcomes changing as the price cap on the second-cheapest Silver plan in the region for the under 45 is progressively lowered.

Table 13: Robustness of average own-price elasticity (subsidized) to demand model and market size

<table>
<thead>
<tr>
<th>Age</th>
<th>Baseline</th>
<th>Alternative demand models</th>
<th>Construction of potential buyers</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Logit</td>
<td>Logit</td>
<td>Logit</td>
</tr>
<tr>
<td></td>
<td>Control func.</td>
<td>2SLS</td>
<td>BLP</td>
</tr>
<tr>
<td>45-64</td>
<td>-1.496</td>
<td>-1.368</td>
<td>-1.461</td>
</tr>
</tbody>
</table>

Note: Robustness of own-price demand elasticities for different age groups among low-income, subsidy eligible buyers. Details for each specification can be found in Appendix D1. Column (1) are elasticities in the baseline model (see Table 8), the model in column (2) uses IV-2SLS instead of control function, the model in column (3) allows a “BLP” random coefficient on price, the model in column (4) estimates coefficients via OLS adding insurer-times-region fixed effects (equation (53)), the model in column (5) departs from discrete choice and estimates elasticity regressing log-enrollment on log-premium and other controls (equation (54)), columns (6) and (7) show the baseline elasticities when market size in all regions is increased (decreased) by 40%.
